Abstract

This paper illustrates the benefits of a self-tuning PID strategy applied to a proton exchange membrane fuel cell system. Controller parameters are updated on-line, at each sampling time, based on an instantaneous linearization of an artificial neural network model of the process and a General Minimum Variance control law. The self-tuning PID scheme allows managing nonlinear behaviors of the system while avoiding heavy computations. The applicability, efficiency and robustness of the proposed control strategy are experimentally confirmed using varying control scenarios. In this aim, the original built-in controller is overridden and the self-tuning PID controller is implemented externally and executed on-line. Experimental results show good performance in setpoint tracking accuracy and robustness against plant/model mismatch. The proposed strategy appears to be a promising alternative to heavy computation nonlinear control strategies and not optimal linear control strategies.

Keywords

1. Introduction

In last few decades, to reduce greenhouse gases emissions and fossil fuels dependence, numerous renewable energy technologies have been studied. Amidst all of the various environmental friendly solutions, fuel cell systems are one of the promising energy technologies. Fuel cells are electrochemical devices that generate electrical energy from chemical reactants continuously. Due to its high efficiency, fast power response, high power density, low operation temperature and ease of maintenance [1]-[3], the proton exchange membrane fuel cell (PEMFC) appears as a suitable clean energy generator technology for a wide range of applications. However, several bolts,

especially related to its control, still remain to be removed to improve the overall system performance. Indeed, global efficiency improvement, optimal hydrogen and air consumption, and reliable and accurate power response remain challenging control goals.

In the literature, numerous control strategies ranging from PID controllers, state feedback linearizing approaches, dynamic neural network controllers, linear quadratic Gaussian (LG) controllers, to model predictive control (MPC) strategies, have been reported regarding PEMFC control. An indicative only review of the various approaches follows. Huang *et al*. [4] designed a fuzzy PID controller to regulate hydrogen flow rate, resulting in an optimization of hydrogen consumption. Wang and Ko [5] proposed a multivariable robust PID controller, based on a classical PID approach combined to the merits of robust control, to regulate air and hydrogen flow rates. Results obtained showed good performance in terms of stability and efficiency using a simple control structure. Methekar *et al*. [6] considered the fuel cell as a MIMO system and proposed two PID control strategies. Using a steady-state relative gain array (RGA) analysis, these authors showed that hydrogen and coolant inlet flow rates are suitable manipulated variables to control the output power and the temperature of a PEMFC, respectively. Li *et al*. [7] proposed a nonlinear robust control of a PEMFC based on a state feedback linearizing approach. This well-known nonlinear approach allows obtaining a nonlinear control law directly from the dynamic nonlinear model of the process. To improve the robustness of the controller, the authors proposed to add a H_∞ robust control strategy to the state feedback control law. Hatti *et al*. [8] designed a dynamic neural network controller based on the Quasi-Newton-Levemberg-Marquardt algorithm. The authors proposed a setpoint tracking of the reactive power demand considering hydrogen flow as control variable. Hasikos *et al*. [9] proposed an optimization methodology to minimize the hydrogen consumption. This methodology is based on a neural network model including in a Non-Linear Programming optimization problem. Shokuhi-Rad *et al*. [10] developed an approximate predictive control (APC) approach based on a neural network model. At each sample time, a linear model is extracted from the neural network model and a linear controller is designed. In this case, performance of the approach has been evaluated in simulation environment. Wu *et al*. [11] designed a multi-loop nonlinear predictive control scheme using a reduced order model to regulate stack temperature and oxygen excess ratio of the fuel cell in a hybrid energy system. However, the controller has only been tested in simulation environment, and authors underlined that some devices and design have not been taken into account (e.g. hydrogen storage, power management and inverters). Gruber *et al*. [12] developed a model based predictive controller to control the oxygen excess ratio using the compressor motor. Experimental results showed that the proposed strategy stabilized the oxygen excess ratio around the desired value five times faster than the built-in controller. Ziogou *et al*. [13] proposed a nonlinear model-based predictive control (NMPC) approach to track a variable load demands while avoiding oxygen starvation and minimizing hydrogen consumption. To achieve on-line application, the authors developed a tailor-made optimization strategy that discretizes control variables and state variables. The proposed approach has been experimentally tested and exhibited good performance in terms of computational time efficiency and setpoint tracking accuracy. Damour *et al*. [14] proposed a fast NMPC scheme, based on a particular parameterization of the control actions, to decrease the optimization problem dimension and achieve real-time implementation. The proposed strategy, tested in simulation environment, turned out to be a promising candidate to achieve on-line implementation.

Regarding advanced control strategies, the modeling step remains essential and mandatory for the control design. In the literature, a wide variety of models, either mechanistic or black-box, with different levels of complexity, can be consulted. Regarding mechanistic approaches, numerous one-dimensional and multi-dimensional models have been proposed [15]-[27]. However, due to their complexity and heavy computation, most of these models are not suitable for real-time control purposes. In this context, black-box approaches appear as a hopeful alternative. Among the various black-box models solutions, artificial neural network model turns out to be a promising candidate to model PEMFC systems. Saengrung *et al*. [28] investigated the relevance of ANN as predictive models of a commercial PEMFC system (1.2 kW). The authors developed and compared the performance of back-propagation (BP) and radial basis function (RBF) algorithms in terms of speed and accuracy to predict stack voltage and current, using air flow rate and stack temperature measurements as inputs. Sisworahardjo *et al*. [29] developed an ANN model of a portable PEMFC (100 W) considering stack temperature and current as inputs, and hydrogen flow rate, stack voltage and power as outputs. The authors reported that, except the transient voltage response of the ANN model, which is faster than the actual fuel cell, the performance of the ANN model in terms of speed and accuracy is quite satisfactory. In Chavez-Ramirez *et al*. [30], the authors proposed an ANN model of a high power PEMFC (5 kW) using seven inputs to predict cell voltage and cathode

temperature. The authors reported a maximum prediction error of 9.4% in the stack voltage and 5.6% in the stack temperature measurements.

In this paper, a neural model-based self-tuning PID controller is developed to control the output voltage of a PEMFC. Controller parameters are updated on-line, at each sampling time, based on an instantaneous linearization of an ANN model of the process and a General Minimum Variance (GMV) control law. Combining GMV control design with instantaneous linearization allows managing nonlinearities of the process, while avoiding heavy computations. To confirm the reliability and the relevance of this approach, the controller is implemented on-line and experimentally tested on a real fuel cell system. The rest of this paper is organized as follows: Section 2 provides a description of the experimental setup of the fuel cell unit. Section 3 is dedicated to control design—a real-time implementable self-tuning PID algorithm dedicated to the PEMFC output voltage control is detailed, and an ANN model of the PEMFC, dedicated to control purposes, is designed and experimentally validated. In Section 4, the performance of the proposed control strategy, in terms of setpoint tracking accuracy and robustness against plant/model mismatch, is experimentally demonstrated. Eventually, conclusions and prospects are drawn in Section 5.

2. Fuel Cell System Description

In the present work, a 50 cm^2 single home fuel cell assembling, with a commercial membrane electrode assembly (MEA) from Paxitech, is used. The fuel cell is assembled with Teflon glass fiber as seal joints and clamped at 11 Nm bolt torque. Details about the fuel cell assembling optimization can be consulted in a previous work [31]. MEA used for this work is composed of symmetric electrodes (0.5 mgPt·cm^{-2}, Pt 40 wt%/C) with a Nafion® N115 membrane. All experiments are performed on a Fuel Cell Test Station (FCTS) manufactured by Fuel Cell Technologies, Inc. (**Figure 1**).

Figure 1. Fuel cell test station.

The FCTS provides control of flow, temperature, humidity, and pressure for both anode and cathode gases. The station incorporates a programmable DC electronic load and an AC-Impedance measurement system (**Figure 2**). Inlet gas flow rates are controlled using two mass flow controllers, located before the humidifier. Fuel cell temperatures and humidification temperatures are controlled using temperature controllers. Reactant gases are humidified through external water tanks, and desired gas humidification value is reached through the regulation of the water temperature in the humidifiers. An electronic load measures cell output voltage and current. The automatic backpressure systems have two main parts: The first is a diaphragm type regulator that mechanically positions itself to provide the desired backpressure. The second is a transducer that provides the gas to the regulator. The transducer is controlled using the software through a LabJack interface unit that provides a 0 - 5 voltage. This range of voltage corresponds to a 0 - 400 kPa backpressure. The automation of the FCTS is based on a Supervisory Control and Data Acquisition (SCDA) system developed on LabView™-software. The SCDA system allows to acquire and monitor all available data, and to manipulate all system actuators. All measured data are written in a file and can be accessed in real-time, and actuators can be manipulated on-line.

In this study, pure hydrogen and air are used as fuel and oxidant, respectively.

3. Self-Tuning PID Controller Design

3.1. Self-Tuning PID Algorithm

The basic feature of the proposed approach consists in an instantaneous linearization of an ANN model combines with a GMV control law. At each sampling time, coefficients are extracted from the nonlinear ANN using instantaneous linearization to obtain a linearized ANN. Parameters of the PID controller are updated using the previous extracted coefficients and a GMV control law. This strategy allows managing nonlinear behaviors of the process while avoiding heavy computations.

The proposed strategy is based on a classical PID control law:

$$u(t) = k_c \left(e(t) + \frac{1}{\tau_i} \int e(t) \, \mathrm{d}t + \tau_d \frac{\mathrm{d}e(t)}{\mathrm{d}t} \right) \tag{1}$$

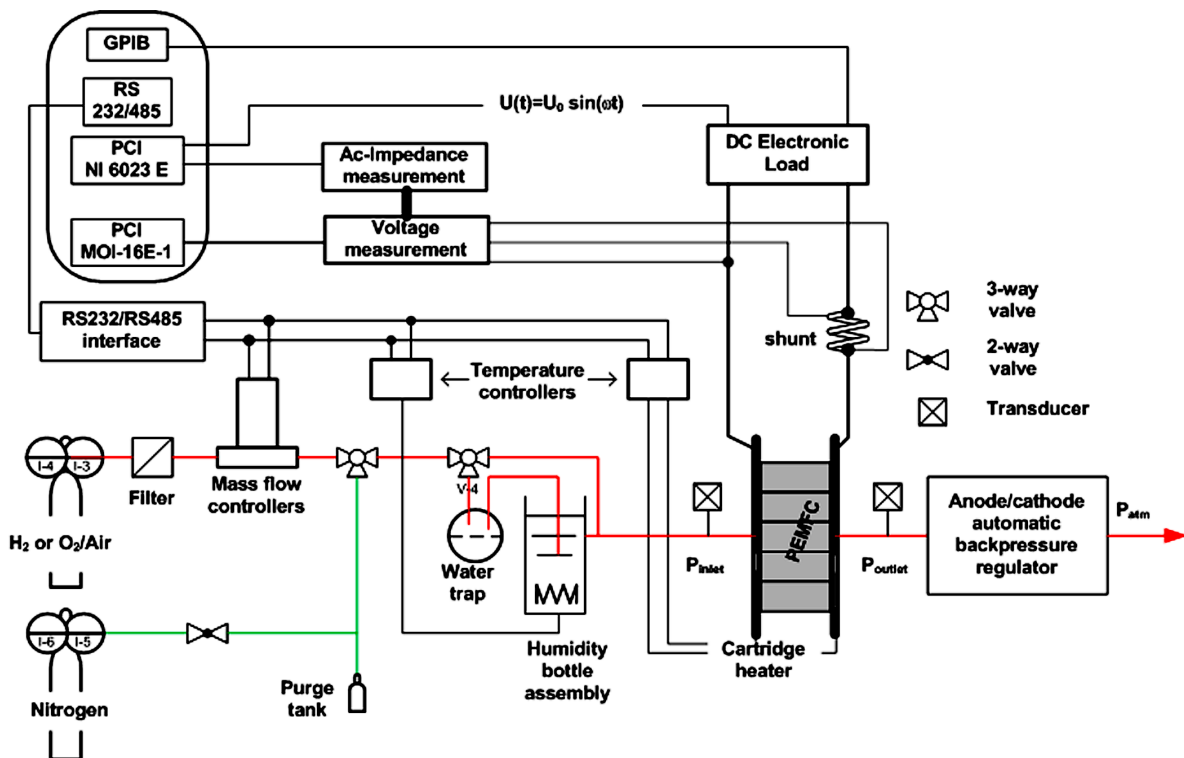

Figure 2. Simplified process and instrumentation diagram of the FCTS system.

where $e(t) = y_{set}(t) - y(t)$ is the trajectory tracking error. k_c, τ_i and τ_d are the proportional gain, the integral time constant and the derivative time constant, respectively.

A velocity form of the discrete PID controller can be written as:

$$u(t) = u(t-1) + \Delta u(t) \tag{2}$$

where $u(t)$ is the control action at time t and $\Delta u(t)$ is written as:

$$\Delta u(t) = k_c \left[\left(e(t) - e(t-1) \right) + \frac{\Delta t}{\tau_i} \left(e(t) + e(t-1) \right) \frac{\tau_d}{\Delta t} \left(e(t) - 2e(t-1) + e(t-1) \right) \right] \tag{3}$$

where Δt is the sampling period, $e(t)$ the trajectory tracking error at time t, and the integral action is computing using trapezoidal approximation.

Rearranging the previous equation, the discrete PID control law can be rewritten:

$$\Delta u(t) = e^{\mathrm{T}}(t) k(t) \tag{4}$$

where $e(t) = \begin{bmatrix} e(t) & e(t-1) & e(t-2) \end{bmatrix}^{\mathrm{T}}$, $k(t) = \begin{bmatrix} k_0 & k_1 & k_2 \end{bmatrix}^{\mathrm{T}}$ and

with $k_0 = k_c \left(1 + \frac{\Delta t}{2\tau_i} + \frac{\tau_d}{\Delta t} \right)$, $k_1 = -k_c \left(1 - \frac{\Delta t}{2\tau_i} + \frac{2\tau_d}{\Delta t} \right)$ and $k_2 = k_c \frac{\tau_d}{\Delta t}$.

In the proposed methodology, the optimization problem is written as:

$$\hat{k} = \arg \min_k (J) \tag{5}$$

where the optimal solution $\hat{k}$ is the set of parameters that minimizes the cost function $J = e^2(t+1) + \mu \Delta u^2(t)$ and μ is a weighting penalty parameter.

However, since $y(t+1)$ is not available at time t, $e(t+1) = y_{set}(t+1) - y(t+1)$ cannot be calculated. To overcome this limitation, $y(t+1)$ is estimated using the linearized ANN model. Therefore, the cost function J can be approximated by the cost function L:

$$J \approx L = \left(e^{\text{lin-ANN}}(t+1) \right)^2 + \mu \Delta u^2(t) \tag{6}$$

where $e^{\text{lin-ANN}}(t+1) = y_{set}(t+1) - \hat{y}^{\text{lin-ANN}}(t+1)$ is the estimated trajectory tracking error and $\hat{y}^{\text{lin-ANN}}(t+1)$ is the output estimated using the linearized ANN model.

It can be demonstrated that the minimization of the cost function L can be achieved using a not iterative procedure. Instantaneous linearization of the ANN and minimization of the cost function are fully detailed in [32] [33].

Finally, PID controller parameters are updated at each sampling time using:

$$\begin{cases} k_c = \frac{1}{2} \left(k_0 - k_1 - 3k_2 \right) \\ \tau_i = \frac{\Delta t \left(k_0 - k_1 - 3k_2 \right)}{2 \left(k_0 + k_1 + k_2 \right)} \\ \tau_d = \Delta t \frac{2k_2}{k_0 - k_1 - 3k_2} \end{cases} \tag{7}$$

3.2. PEMFC ANN Model

This section is dedicated to the PEMFC ANN model design. This model is expected to predict the output voltage of the PEMFC one step ahead once the load current is available.

In this aim, various network architectures have been investigated to determine which one will provide the best prediction in terms of computational speed and accuracy. After comparing several architectures, a fully connected three layers feed forward network is retained. The input layer consists of one input, namely load current. The hidden layer has five neurons with tangential sigmoid activation function φ_1. The output layer, composed

of 1 neuron with linear activation function φ_2 , provides the cell output voltage.

Regarding ANN model identification, the choice of the training data set is a quite important feature. Indeed, since ANN model performs better in interpolation than in extrapolation the training data set needs to cover a large range of operating conditions from minimum inputs/outputs values to maximum inputs/outputs values.

In the following, two sets of experimental data, sampled with a 3-second period and collected from the PEMFC system described in Section 2, are used. The training phase is performed on the first set using Levenberg-Marquardt algorithm with an error goal of 0.001, whereas the validation step is based on the second one (**Figure 3**).

Prediction performance of the ANN model is investigated using three criteria: the root mean squared error (RMSE), the absolute mean error (AME) and the absolute maximal error (AE$_\infty$). RMSE and AME are used to evaluate the model accuracy, whereas AE$_\infty$ represents the worst case in terms of prediction accuracy:

$$\text{RMSE} = \frac{\sqrt{\sum_{i=1}^{n}\left(y^{(i)} - \hat{y}^{(i)}\right)^2}}{n} \tag{8}$$

$$\text{AME} = \frac{\sum_{i=1}^{n}\left|\left(y^{(i)} - \hat{y}^{(i)}\right)\right|}{n} \tag{9}$$

$$\text{AE}_\infty = \max_{i=1}^{n}\left(\left|y^{(i)} - \hat{y}^{(i)}\right|\right) \tag{10}$$

y represents the experimental values, $\hat{y}$ is the simulated data obtained using the ANN model and n is the number of data.

Prediction accuracy results of the proposed ANN model are summarized in **Table 1**.

Considering that the ANN model is dedicated to control purposes, the prediction accuracy performance is considered quite satisfactory.

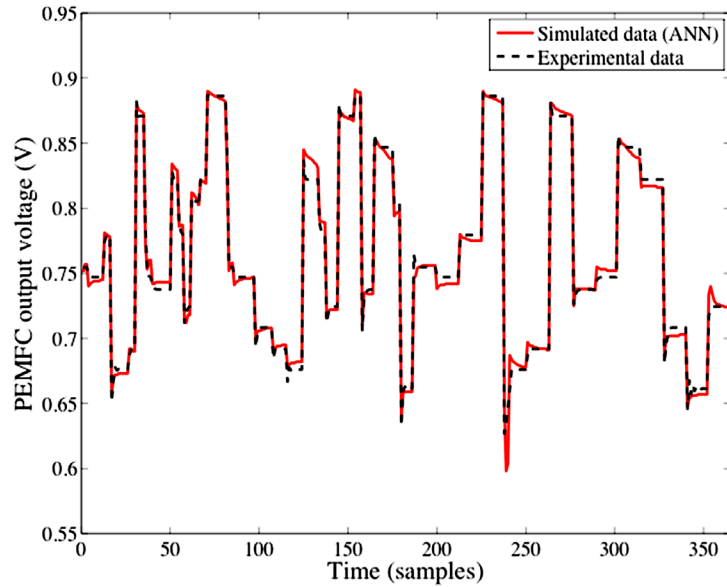

Figure 3. ANN validation.

Table 1. Training and validation results.

	Training	Validation
RMSE (V)	3.3281×10^{-4}	0.0011
AME (V)	0.0044	0.0082
AE$_\infty$(V)	0.0419	0.0787

Figure 6. Zoom in on **Figure 5**.

Table 2. Experimental setpoint tracking performance of the proposed PID controller.

	Case 1: $\mu = 5 \times 10^{-2}$	Case 2: $\mu = 3 \times 10^{-2}$	Case 2: $\mu = 1 \times 10^{-2}$
RMSE (V)	8.9157×10^{-4}	6.1746×10^{-4}	6.1655×10^{-4}

Figure 5 and **Table 2** illustrate the control effectiveness of the self-tuning PID controller for different values of μ. The proposed control strategy shows excellent accuracy in voltage setpoint tracking regardless of the value of the μ, which emphasizes among other things its robustness against plant/model mismatch.

However, even if the overall setpoint tracking accuracy remains the same whatever the value of μ, it is important to notice that the value of μ is strongly correlated with the overshoot. As illustrates on **Figure 6**, a decrease of the value of μ involves an increase of the overshoot.
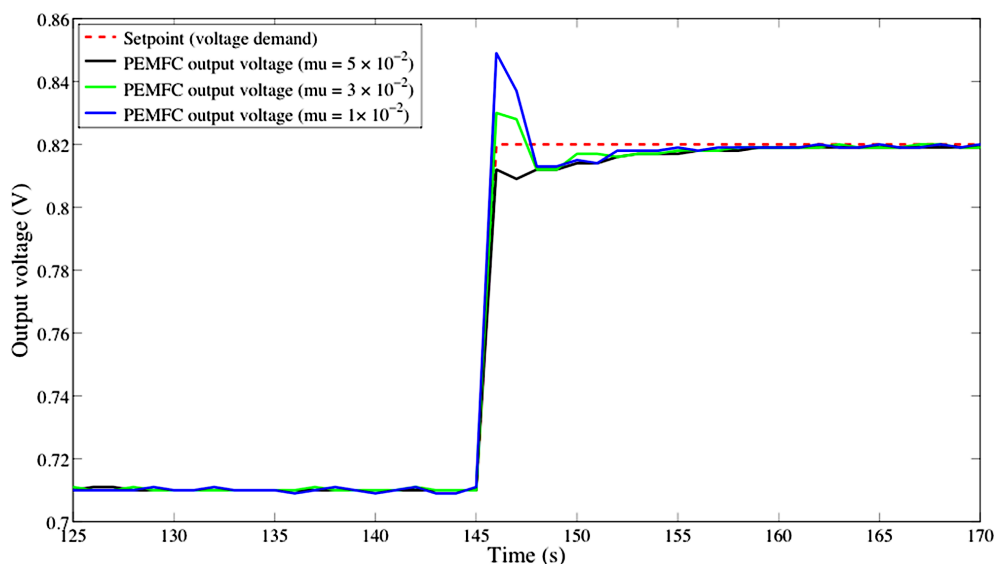

5. Conclusion and Prospects

In this work, a neural model-based self-tuning PID controller has been designed and experimentally tested on-line to control the output voltage of a PEMFC. Controller parameters have been updated on-line, at each sampling time, based on a linearized ANN model and a GMV control law. Combining GMV control design with instantaneous linearization allowed managing nonlinearities of the process, while avoiding heavy computations.

In a first stage, an artificial neural network model, expected to predict output voltage of the PMEFC, has been designed and experimentally validated. In a second stage, the performance of the proposed strategy has been evaluated through several experiments. In this aim, the original built-in controller has been overridden and the self-tuning PID controller has been implemented externally and executed on-line. Experimental results demonstrated the efficiency of the proposed approach in terms of setpoint tracking accuracy and robustness against plant/model mismatch.

Regarding fast dynamic nonlinear systems, such as PEMFC, the proposed self-tuning PID strategy turned out to be a promising alternative to heavy computation nonlinear control strategies and not optimal linear control strategies.
