## ABSTRACT

**Detecting volcanic unrest is of primary importance for eruption forecasting, especially on volcanoes characterized by highly dangerous, and often seemingly unpredictable, phreatic or phreatomagmatic eruptions. We present a simple and innovative analysis of shallow vertical temperature profiles to depths of 70 cm. These data were recorded at La Fossa cone of Vulcano (Aeolian Islands, Italy), during an episode of increased hydrothermal and seismic activities that occurred between September and December 2009. This work involves the use of the coefficient of determination ( $R^2$ ) on vertical temperature profiles in order to identify changes in conductive versus convective heat transfer modality. The increase in convective heat transfer can be related to the disruption of the hydrothermal system due to its pressurization and/or variation of ground permeability between the hydrothermal system and the surface. While raw temperature data do not evidence any significant variation during the period investigated and the classic temperature gradient is highly influenced by seasonal variations, the fluctuation of  $R^2$  displayed striking spikes that coincided with the seismic swarm inside the volcanic edifice. Such a low-cost device associated with easy real-time data processing could constitute a very promising, yet deceptively simple, technique to monitor hydrothermal systems, in order to assess the hazard posed by high-energy eruptions for populations living close to active volcanoes.**

## INTRODUCTION

Hydrothermal systems are characterized by important mass and energy transfer through the circulation of hot fluids underground that can be evidenced by geological, geophysical, or geochemical observations. One consequence of hydrothermal circulation is the alteration and weakening of the permeable ground inside volcanic edifices. Hydrothermal alteration greatly decreases the permeability of the medium and disrupts fluid circulation through self-sealing processes. Such modifications may increase pore pressure, the changes in which hydrothermal systems give an indication about the general state of volcanic unrest, and sometimes promote highly hazardous explosive phreatic or phreatomagmatic eruptions (Heiken et al., 1980; Barberi et al., 1992; Germanovich and Lowell, 1995; Ui et al., 2002; Starostin et al., 2005; Fournier and Chardot, 2012).

Studying variations in hydrothermal system activity is crucial to exploring their role in, and potential to forecast highly explosive activity. Therefore, identifying the key parameters that indirectly highlight the state of pressurization of the system is necessary to develop early warning of highly explosive eruptions. Temperature is perhaps the easiest and most obvious observable variable, and can be measured with soil temperature sensors, infrared cameras, or satellite-based multispectral infrared images (Gaudin et al., 2013).

Unfortunately, the change in temperature in hydrothermal system fluids is not an easy parameter to use in identifying precursors of volcanic

unrest. Temperature is affected by many external parameters, such as daily and seasonal variations, rainfall, and wind speed and direction (Dawson and Fisher, 1964; Keszthelyi et al., 2003; Chiodini et al., 2005; Hochstein and Bromley, 2005; Peltier et al., 2012).

The aim of this paper is to propose an innovative method to process soil temperature time series that could be used in volcano observatories for real-time monitoring. This new technique can identify disruptions of hydrothermal fluid flow that potentially lead to volcanic unrest.

## APPLICATION SITE AND INSTRUMENTATION

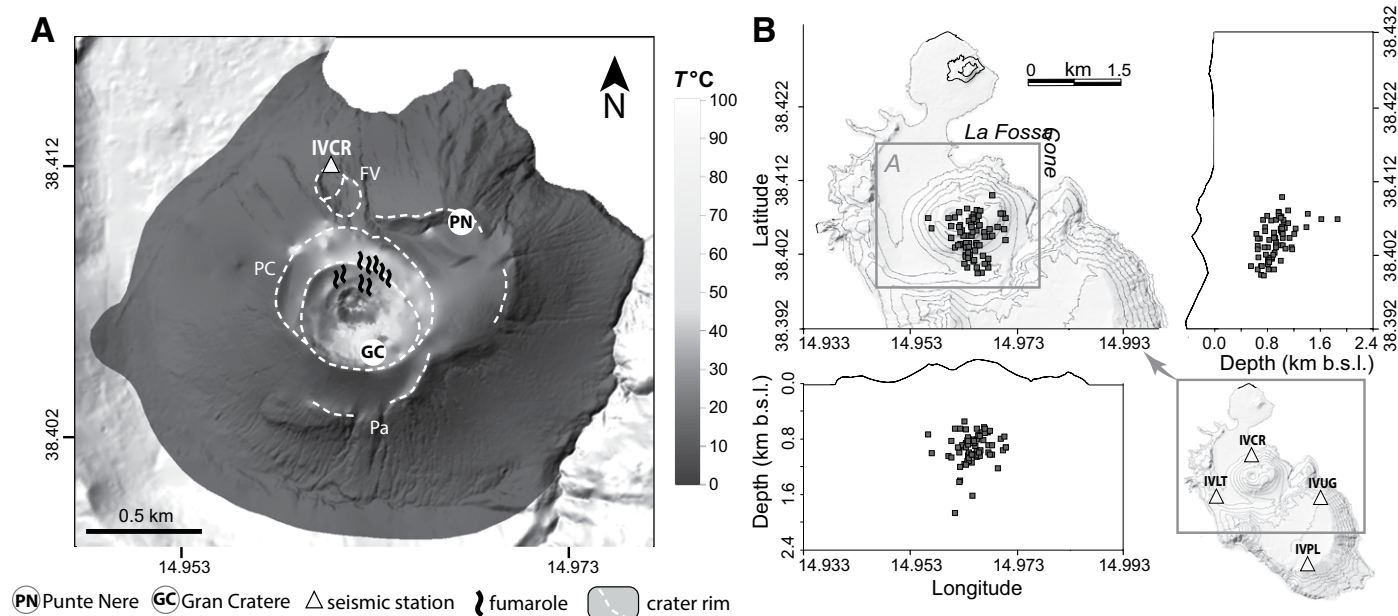

The test site where our temperature instrumentation was installed is La Fossa cone on Vulcano Island (Aeolian Islands, Italy), because of its persistent fumarolic activity, the presence of subfumarolic areas (documented in previous studies; e.g., Revil et al., 2008; Barde-Cabusson et al., 2009), and the recurrence of fumarolic crises during the past few decades (Chiodini et al., 1992; Granieri et al., 2006).

La Fossa cone, formed in the past 6 k.y. on the island of Vulcano, provides the historic basis for the term Vulcanian-type phreatomagmatic explosive eruptions, which are characterized by water-magma interaction (Frazzetta et al., 1983; Büttner et al., 1999; Dellino et al., 2011). The structure of the present-day edifice results from six main phases of activity (De Astis et al., 2006), chronologically associated with crater boundaries: (1) Punte Nere, (2) Palizzi, (3) Forgia Vecchia, (4) Pietre Cotte, and (5) Gran Cratere (Fig. 1A). Each of these structural boundaries is associated with relevant temperature anomalies identified through measurements at 30 cm depth (Revil et al., 2008; Barde-Cabusson et al., 2009), highlighting the major role of these crater ring faults in channeling hydrothermal fluids toward the surface.

Two sites of anomalous temperature were chosen for the installation of our instrumentation that correspond to two structural boundaries located outside the main fumarolic field of La Fossa crater (see Fig. 1A): (1) Gran Cratere (GC in Fig. 1A) and (2) Punte Nere (PN in Fig. 1A), located 250 m and 600 m, respectively, from the last eruptive crater.

We used an Ebro Electronic EBI-2T type 313 data logger to monitor the temperature in the soil. The device temperature range is  $-40$  to  $+150$  °C, with 4 channels and 4 PT1000 sensors (resolution is 0.1 °C and measuring accuracy is 0.2 °C). The temperature sensors were placed at the precise depths of 10, 30, 50, and 70 cm (see Fig. DR1 in the GSA Data Repository<sup>1</sup>) in areas where the soil temperature at 70 cm depth ranged between 70 and 80 °C. It is essential to avoid areas where the temperature signal is saturated by the buffering effect of steam present at boiling temperatures.

<sup>1</sup>GSA Data Repository item 2015319, temperature monitoring stations, seismicity related to fluid dynamics within the hydrothermal system of La Fossa cone of Vulcano, and heat transfer at shallow depth, is available online at [www.geosociety.org/pubs/ft2015.htm](http://www.geosociety.org/pubs/ft2015.htm), or on request from [editing@geosociety.org](mailto:editing@geosociety.org) or Documents Secretary, GSA, P.O. Box 9140, Boulder, CO 80301, USA.

**Figure 1.** Locations of crater boundaries, temperature data loggers, seismic network, and hypocenters of the 2009 seismic crisis at La Fossa cone (Vulcano, Aeolian Islands, Italy). **A:** Location of the two temperature data loggers over the soil temperature ( $T$ ) map (measured at 30 cm depth). Pa—Palizzi, FV—Forgia Vecchia, PC—Pietre Cotte, IVCR—location of the Istituto Nazionale di Geofisica e Vulcanologia (INGV) permanent seismic station at La Fossa cone. **B:** Location of INGV permanent seismic stations (triangles) operating at Vulcano Island, used to locate the hypocenters of the 2009 seismic crisis, and the seismic events (squares) during the 2009 seismic crisis at La Fossa cone (b.s.l.—below sea level).

Since its last magmatic eruption (A.D. 1888–1890), La Fossa crater has been affected by two main episodes of increased fumarolic activity and temperature. The first occurred during the period 1913–1923 (Sicardi, 1940), and the second began in 1978 after a M 5.5 earthquake (Chiodini et al., 1992). Relevant changes in the fumarolic composition occurred in 1979–1981, 1985, 1988, 1996, and in December 2004 and 2005 (Granieri et al., 2006; Carapezza et al., 2011).

At Vulcano, seismicity is associated with volcano-tectonic sources or is related to fluid dynamics within the hydrothermal system (Aubert et al., 2008; Cannata et al., 2012; Madonia et al., 2013). The first case is generally related to the north-northwest–south-southeast Tindari-Letojanni regional fault system dynamics (Gambino et al., 2012) and results in a few events per year, while the second comprises seismovolcanic events occurring in the hydrothermal system underlying La Fossa cone, from several hundred to thousands per year (Alparone et al., 2010; Milluzzo et al., 2010; see the Data Repository).

We compared seismic data with our results, because seismic swarms suggest the disruption of the hydrothermal system, an increase of the permeability inside the edifice, and consequently an increase of hot fluids flow toward the surface (Cannata et al., 2012; Milluzzo et al., 2010).

During our experiment, seismicity detected by the Istituto Nazionale di Geofisica e Vulcanologia seismic network (Fig. 1B) was characterized by a seismic swarm that occurred at shallow depth below La Fossa cone between 29 September and 16 December 2009 (Fig. 2E). During this seismic swarm, 3471 seismic events were detected in 79 days (an average of 43.9 events/day versus 11.2 events/day characterizing the period before the swarm). Due to the very low energy released, the identification of hypocenters was possible only for the 72 (2.1%) most energetic seismic events, mainly located between 600 and 1200 m below sea level. In terms of number of events per day, this seismic swarm was the most important of the past two decades (Harris et al., 2012). At the same time, several geochemical parameters increased by one order of magnitude, such as soil  $\text{CO}_2$  flux and  $\text{SO}_2$  in the plume, indicating disruptions in the underlying magmatic system (Inguaggiato et al., 2012).

## RESULTS

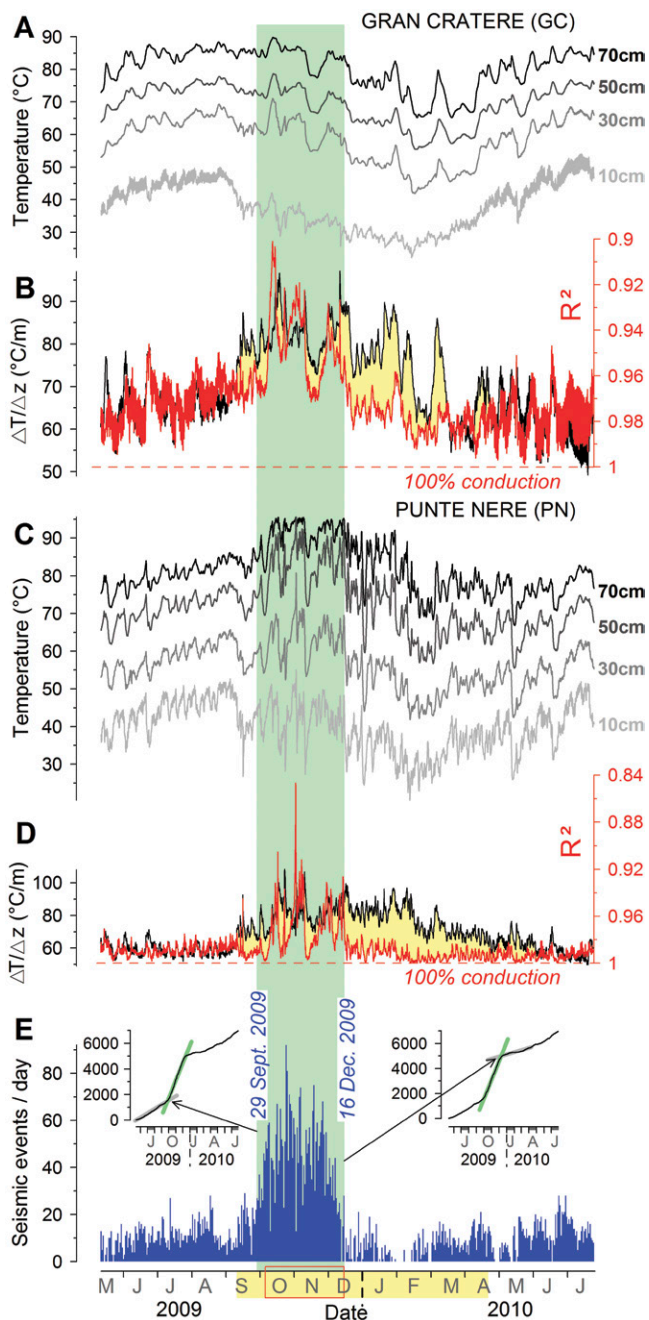

Raw data for soil temperature recorded at Gran Cratere (GC) and Punte Nere (PN) in the period 12 May 2009–28 July 2010 (Figs. 2A and 2C) displayed, at both sites, a classic pattern of environmental temperature variations (periodic long-term seasonal variations, and short-term daily variations) disrupted by rainfall events. At the GC site, no temperature variation could be associated with the 2009 seismic swarm. At the PN site, however, only a weak variation of the signal coincided with changes in the seismicity, although there was no clear evidence to support this. In contrast, the temperature gradients calculated between 70 and 10 cm depths displayed a strong seasonality at both sites, preventing any possibility of clearly detecting disruptions related to hydrothermal activity (Figs. 2B and 2D). Despite the fact that we can note changes in the temperature gradient coinciding with variations of coefficient of determination,  $R^2$ , at both sites, other changes of the same amplitude in the temperature gradient also appear outside the seismic swarm period. This means that changes in temperature gradient are not exclusively related to hydrothermal system disruptions, and they remain unclear due to a low signal-to-noise ratio.

In order to determine if the 2009 seismic swarm influenced the heat transfer modalities inside La Fossa cone, we computed a linear regression of temperature versus depth and  $R^2$  at each site and time interval. The aim of this analysis was to discriminate the conductive-dominated heat transfer from a more convective one (see the Data Repository); the former is characterized by a linear gradient of  $R^2 \sim 1$ , and the latter is characterized by a nonlinear gradient giving lower  $R^2$  values.

Applying an  $R^2$  analysis to our vertical temperature profiles (Figs. 2A and 2C), we obtained the results shown in Figures 2B and 2D. At both GC and PN sites, significant anomalous spikes of  $R^2$  coincide with the seismic swarm, showing an obvious disruption in the hydrothermal fluid flow.

## DISCUSSION

The comparison between the raw temperature data and the  $R^2$  variations obtained in the same data set displays striking results because no

**Figure 2.** Temperature variations, coefficient of determination ( $R^2$ ), and seismic events. **A:** Raw temperature data measured at 10, 30, 50, and 70 cm depth at Gran Cratere (Vulcano, Aeolian Islands, Italy) during the period 12 May 2009–18 July 2010. **B:** Coefficient of determination (in red) and temperature gradient between 70 and 10 cm depth (in black and yellow) calculated on the temperature data set for the same period for Gran Cratere.  $z$  is depth of temperature sensors. **C:** Temperature data measured at Punte Nere (Vulcano, Aeolian Islands, Italy). **D:** Coefficient of determination (in red) and temperature gradient between 70 and 10 cm depth (in black and yellow) calculated on the temperature data set for the same period for Punte Nere. **E:** Number of seismic events recorded at the IVCR station, with the relative cumulative curves. Green area represents the period of seismic crisis evidenced by the cumulative curve of seismicity. The coefficient of determination allows distinguishing the evolution from a conductive to a convective heat transfer induced by a disruption of the hydrothermal system during the seismic crisis.

temperature anomaly is obvious in the raw data during the period of seismic swarm. The main external parameters influencing the superficial soil temperature were daily and seasonal temperature variations and contrast between sunshine and cloudy periods. Each one of these parameters is related to pure heat conduction in the soil, and therefore exhibit  $R^2 \sim 1$  despite substantial changes in temperature. These three external parameters have a different influence on temperature values measured by each individual sensor, as shown by the temperature gradient variations (Figs. 2B and 2D). Conversely, they do not significantly affect the heat transfer modality (conductive versus convective) of the heat toward the surface, driven mainly by the energy released at depth by the hydrothermal system. Although these external processes strongly modify the temperature values, they do not disrupt the linearity of the temperature gradient as a function of depth. In this sense, the  $R^2$  analysis constitutes an excellent filter for these external parameters and allows for extracting variations related to convective heat transfer of deep origin.

Rainfall is among the external parameters that influence temperature values. Rainfall corresponds to an injection of a cold fluid into the soil, which decreases the temperature and makes the top of the condensation zone deeper (see the Data Repository). As a consequence, the thickness of the conductive zone located above the condensation level increases, as well as  $R^2$ . It can take from several days to a few weeks before a temperature disruption induced by a rainfall vanishes and the temperatures return to their initial values (Chiodini et al., 2005; Peltier et al., 2012). The duration of the disruption depends on the intensity of the rain and the geothermal energy released from the soil. Although rain events appear to have more significant consequences on the convective component, it is interesting to note that the external parameters previously described (seasonal and diurnal variations and strong sunshine periods) do not disrupt the signal toward a more convective end member. Therefore, a decrease of  $R^2$  is basically the result of an increase in the advective hydrothermal fluid flow toward the surface.

Moreover, unlike remote techniques used for temperature detection (e.g., infrared camera or infrared channels of satellite images), cloudy weather has no adverse effect on the acquisition of soil temperature data, representing a real advantage in thermal monitoring of active volcanoes.

The seismic swarm began 9 days before the decrease of  $R^2$  values, on 29 September and 8 October, respectively. This time delay suggests that the disruption of the hydrothermal fluid flow at the surface could be a consequence of the seismic swarm. Small perturbations temporarily increasing the pore pressure can modify the effective normal stress and trigger seismicity. This phenomenon and other fracturing processes (due to alteration of rock to secondary minerals by reducing the shear stress required to initiate fracturing and/or increases in temperatures in the rock and consequent rock fracturing) are also able to enhance the rock's vertical permeability, thus favoring the rise of fluids (Cannata et al., 2012, and references therein).

## CONCLUSIONS

Our results indicate that monitoring the linearity of the vertical temperature profiles at shallow depths (to 70 cm), and therefore the changes from conductive to convective heat transfer in the near surface, is an efficient tool for the identification of volcanic unrest associated with disruption of a hydrothermal system. The installation of such a simple temperature monitoring device could be considered by volcano observatories because it gives fundamental information on changes of heat transfer modality not highlighted by ordinary thermal monitoring. Moreover, data processing can be easily integrated into a real-time monitoring for surveillance purposes. An increase of the hydrothermal activity can be related to pressure and/or permeability changes inside the edifice, potentially leading to explosive activity. Such information is of prime importance for eruption forecasting and hazard assessment and, ultimately, volcanic risk mitigation.

## ACKNOWLEDGMENTS

This work has been supported by the University of La Réunion–Institut de Physique du Globe de Paris (IPGP) and the CNRS-INSU (Centre National de la Recherche Scientifique, Institut National des Sciences de l'Univers) project, and a one-month IPGP (Institut de Physique du Globe de Paris) Invited Researcher program for Ricci in the Laboratoire GéoSciences Réunion.
