ABSTRACT

On October 1st, 2005, Santa Ana volcano (El Salvador) underwent a VEI 3 phreatomagmatic eruption after approximately one century of rest. Casualties and damages to some of the local infrastructures and surrounding plantations were followed by the evacuation of the nearby communities. The analysis of MODIS (Moderate Resolution Imaging Spectroradiometer) infrared data reveals that the main explosion was preceded by a one-year-long thermal unrest, associated to the development of a fumaroles field, located at the western rim of the summit crater lake. By combining space-based thermal flux and ground-based measurements (seismicity, sulfur emissions and lake temperatures), we suggest that the activity observed at Santa Ana between 2004 and 2005 was driven by the gradual intrusion of an undegassed magma body at a very shallow depth. Magma injection induced thermal anomalies associated with sustained degassing from the fumaroles field and promoted the interaction between the magmatic-hydrothermal system and the overlying water table. This process culminated into the VEI 3 phreatomagmatic eruption of October 2005 that strongly modified the shallow structure of the crater area. The subsequent three-years-long activity resulted from self-sealing of the fracture system and by the opening of a new fracture network directly connecting the deeper hydrothermal system with the crater lake. Our results show that satellite-based thermal data allow us to detect the expansion of the high-temperature fumarolic field. This may precede an explosive eruption and/or a lava dome extrusion. In particular, we show that thermal records can be analyzed with other geochemical (i.e. SO₂ emissions) and geophysical (seismicity) data to track a shallow magmatic intrusion interacting with the surrounding hydrothermal system. This provides a remarkable support for volcano monitoring and eruption forecasting, particularly in remote areas where permanent ground data acquisition is hazardous, expensive and difficult.

1. Introduction

Thermal monitoring of a fumarolic area is a key tool to track changes in hydrothermal systems which lay in the surrounding of magma bodies (Chiodini et al., 2007; Shinohara et al., 2015; Fischer et al., 2015; Ricci et al., 2015). Intense degassing, characterized by a marked fumarole activity, is usually associated with variations in volcanic activity (e.g. phreatic eruptions) which, in turn, may coexist with the extrusion (and/or growing cycles) of a lava dome (Barberi et al., 1992; Kaneko and Wooster, 1999; Stevenson and Varley, 2008; Ball et al., 2013; Phillipson et al.,

2013). On the whole, fumaroles hosted within or around a crater lake may show signs of volcanic unrest. These are generally coupled with chemical variations in fluid composition and color changes of the water lake (Németh et al., 2006; Shinohara et al., 2015; Fischer et al., 2015).

Although satellite thermal data have been increasingly used to monitor active volcanoes (Ramsey and Harris, 2012; Harris, 2013; Coppola et al., 2016a), the detection of small thermal anomalies (e.g. lacking of a direct magma exposure at the surface) remains a rather challenging task in volcanology (cf. Coppola et al., 2016b). In fact, fumaroles and other low thermal signals are cooler (when compared with magma temperatures), and smaller (with respect to hot lava flows and domes). However, high spatial resolution sensors (TM class sensor with 30–90 m pixel resolution; cf. Harris, 2013 classification), recording data in the Thermal

InfraRed (TIR) region of the electromagnetic spectrum, have been generally used to collect systematic measurements (Oppenheimer, 1993, 1996, 1997; Trunk and Bernard, 2008; Bodruddoza Mia et al., 2014). However, despite these results being reliable and encouraging, TM class sensors provide data with a relatively poor temporal resolution (~16 days at most) and may miss short term fluctuations or the detection of important events (i.e., at their onset). Conversely, the AVHRR class sensors may provide several images per day (with 1 km pixel resolution on IR bands; see Harris, 2013 classification) and have greatly improved the capability to detect and track remote eruptive events (Dean et al., 1998; Dehn et al., 2002; Patrick et al., 2005) as well as to identify hot fumaroles activity (Vulcano Island; Harris and Stevenson, 1997). In particular MODIS (Moderate Resolution Imaging Spectroradiometer) data, providing four overpasses per day at the equator, represents a valuable tool for detecting low magnitude thermal anomalies on poorly monitored and/or remote active volcanoes (Coppola et al., 2015, 2016b, 2016c).

In this paper, we present the thermal activity at the Santa Ana volcano achieved by processing the 2000–2015 dataset of nighttime MODIS images with the MIROVA algorithm (cf. Coppola et al., 2016a). The retrieved thermal flux jointed with ground based data (performed by the UES Universidad de El Salvador and the MARN Observatorio Ambiental del Ministerio de Medio Ambiente y Riesgos Naturales) allowed us to draw a reliable timeline of the unrest phases which were preceding the major explosion of Santa Ana on October 1st, 2005. Our results delineate the complex relationships occurring among the shallow level magma body, hydrothermal degassing and crater lake activity.

2. Santa Ana volcano

Santa Ana (13°51'N, 89°37'W) is the most active volcano of El Salvador and one of the main of the Central America. The 2381 m high Santa

Ana volcano (locally named Iamatepec), is part of the Coatepeque Izalco Santa Ana volcanic complex that lies at the intersection of the NW–SE regional faults system and the southern rim of the so called Median Trough depression of Plio–Pleistocene age (Fig. 1a; Mooser et al., 1958; Pullinger, 1998).

At least 12 eruptive episodes occurred at Santa Ana volcano since the 16th century. These events were mainly characterized by phreatic and phreatomagmatic eruptions (VEI 2–3; Simkin and Siebert, 1994) and were sporadically accompanied by lava flow outpouring from the summit or from secondary cones aligned NW–SE (Pullinger, 1998).

The summit part of the Santa Ana volcano consists of four concentric craters, the largest one reaching a diameter of 1.5 km, and the innermost one (on the SE) with a radius of about 0.5 km (Fig. 1b, c). This latter is the youngest and was formed after the 1904 eruption (Carr and Pointer, 1981). It hosts an acidic crater lake with a chemical composition that reflects the interaction between the magmatic, hydrothermal and phreatic systems (Bernard et al., 2004; Scolamacchia et al., 2010).

In terms of risk assessment, it must be emphasized that nearly 1 million of people live within an area with an approximate radius of 25 km from the summit crater. This drastically increases the hazard due to the occurrence of lahars and ash falls, capable of seriously damaging local infrastructures and agriculture (Pullinger, 1998).

No sign of volcanic activity has been noticed for Santa Ana since the 1904 eruption (Mooser et al., 1958; Bernard et al., 2004). However, since 2000, the western sector of the crater lake was periodically surrounded by a high temperature fumarolic area (see Fig. 1b, d), testifying the existence of a shallow, well developed hydrothermal system (Bernard et al., 2004; Rodríguez et al., 2004). The increase in the hydrothermal activity was marked by an intense degassing and glowing fumaroles (from 550 °C to 875 °C), as well as by changes in the water

Fig. 1. (a) Simplified tectonic sketch of the Central American region (from Fernandez et al., 2004 simplified); (b) the four concentric craters rim and the crater lake hosted by the youngest. The surrounding fumaroles' field (red area) and the location of the seismic station (white square) were also reported. View from Google Earth; (c) Overhead view of the summit area of the Santa Ana volcano; (d) Image on Panchromatic channel (15 m. resolution) acquired by Landsat ETM+ on March 6th, 2001; yellow star shows the location of temperature measurements in the fumaroles' field (see text for details).

temperature of the lake (from 18 °C to 30 °C) (cf. Bernard et al., 2004; Global Volcanism Program, 2001). Thereafter, the Santa Ana volcano has shown progressive signs of unrest that culminated into the VEI 3 explosion of October 1, 2005 (Colvin et al., 2013).

After this major event, the activity was focused exclusively into the crater lake and consisted of evaporation cycles, increases in water lake temperatures, physico chemical changes and sporadic phreatic explosions (Hernández et al., 2007; Colvin et al., 2013). Since early 2008, the Santa Ana summit lake seems to have entered in a relative quiet phase, defined by the stability in color, volume and temperature of the water lake (cf. Colvin et al., 2013). Here, we focus on a multiparametric analysis of the activity characterizing the Santa Ana volcano between 2004 and 2007, with a special emphasis on the unrest phase preceding the October 1, 2005 explosion.

3. Datasets

The datasets used in this paper consist of: i) Volcanic Radiative Power; ii) SO₂ flux, iii) tremor amplitude (in terms of RSAM); (iv) daily number of the Long Period and (v) daily number of Volcano Tectonic events and (vi) crater lake temperature (Fig. 2).

3.1. Space based thermal data the MIROVA algorithm

MIROVA (Middle InfraRed Observation of Volcanic Activity; see Coppola et al., 2016a) is a global volcanic hotspot detection system that combines a moderate temporal and spatial resolution (4 images per day; 1 km pixel resolution) with a high efficiency in detecting small hotspots (~1 MW). These features enable the system to locate

Fig. 2. 2004–2007 time series of the acquired parameters at the Santa Ana volcano. The red thick dotted line marks the October 1st, 2005 eruption, the yellow stars indicates the two main phreatic explosions (June 15th, 2005 and April 27th, 2007). The dotted bars represent the limits of the temporal phases described in the text. The a–d represent the sub-phases of the Phase I (Unrest state).

and quantify the heat generated by a large variety of volcanic activities on a daily basis (www.mirovaweb.it).

MIROVA uses Middle InfraRed (MIR) data acquired by Moderate Resolution Imaging Spectroradiometer (MODIS) sensor, mounted on board of Terra and Aqua NASA's satellites (launched on February 2000 and May 2002, respectively). The MODIS images (1 km² of resolution in the IR bands), are automatically processed by a hybrid algorithm, where each single image is managed to: (i) produce 50 × 50 km NTI maps centered on the volcano summit; (ii) detect the presence of sub pixel, high temperature hot spot(s), and (iii) quantify the Volcanic Radiative Power (VRP in Watt) associated to the hot source (see Suppl. Materials; Coppola et al., 2016a).

3.2. Seismic measurements

Seismicity was detected on a telemetered seismic station equipped with an LLC Short period Seismometer Model S 13/GS 13 (Geotech Instruments), vertical component maintained by SNET technics. During the analyzed period, high frequency Volcano Tectonic (VT) and Long Period (LP) events were registered and related to the summit activity of the Santa Ana volcano. Tremor amplitude was elaborated in terms of RSAM (Real Time Seismic Amplitude Measurements) by considering a value of 20 units as the baseline for the analyzed area (cf. Olmos et al., 2007).

3.3. SO₂ flux measurements

The daily SO₂ were obtained by a NOVAC Scanning DOAS system (Scanning Dual beam miniature Differential Optical Absorption Spectroscopy system) (Galle et al., 2002). The instrument is composed of one miniaturized spectrometer (Ocean Optics Inc.), embedded PC, an optical fiber, a telescope and a GPS receiver. The Optic Spectrometer detects UV (ultraviolet) light and converts it to digital signals. The signals are the spectra for later gas evaluation. The telescope collects the ultra violet light scattered from aerosols and molecules in the atmosphere. Controlled by the motor, it is able to turn in 360°. The optical fiber transfers light from the telescope to the spectrometer. The motor controls the angle of the telescope. It moves the telescope to perform certain steps, according to the command from the embedded PC. The GPS receiver records the position of the system and gives out the universal standard

time. The embedded single chip PC collects the spectra and manages communication.

3.4. Lake temperature measurements

Lake temperature has been measured every 24 h with digital Logger sensor thermometers (range: −20 +50 °C and accuracy of ±0.4 °C) placed in the middle of the lake, at a depth of 1 m. Due to the difficulty experienced to maintain the efficiency of this set up instrumentation in an area such as the summit of Santa Ana volcano, the reported dataset suffered some long time period data gaps.

4. The 2004–2007 eruptive activity at Santa Ana volcano

Here we combine the satellite thermal data, obtained by using the MIROVA system, with the geophysical and geochemical parameters acquired by the U.E.S. and M.A.R.N. at the Santa Ana volcano between 2004 and 2007 (Fig. 2). Visual observations and periodic field surveys on the summit area (see Figs. 3, 6) have been used to describe the summit activity and to support the interpretation of the monitored parameters.

On the whole, the analyzed period has been subdivided into three main phases that include: (i) a phase of volcanic unrest (2004–2005), culminated with (ii) the VEI 3 October 1st, 2005 phreatomagmatic explosion that was followed by (iii) a period of frequent physico-chemical changes of the crater lake (2006–2008) coupled with sporadic phreatic explosions (cf. Colvin et al., 2013). Particularly, the combined analysis of the seismic, thermal and geochemical data allows us to follow the evolution of the eruptive crisis and to subdivide the initial unrest phase into four distinct sub-phases (Ia to Id) (Figs. 2 and 5).

4.1. Phase I (June 1st, 2004–September 30th, 2005): unrest

Until the end of May 2004, the Santa Ana volcano had exhibited a lack of seismicity, absence of space-based thermal anomalies, with the crater lake temperature spanning between 18 and 25 °C and relatively stable SO₂ emissions of below 600 T/d (see Fig. 2; Colvin et al., 2013).

4.1.1. Phase Ia (June 1st, 2004–September 20th, 2004)

Since June 2004 (Phase Ia), we started to record Long Period (LP) events and volcano tectonic (VT) swarms, indicating that the Santa

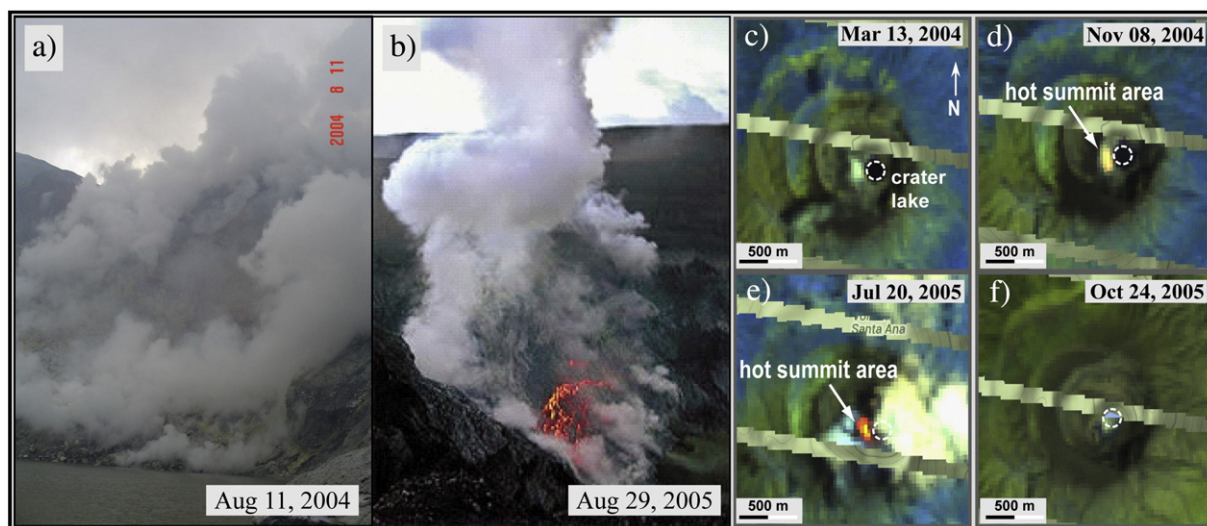

Fig. 3. Photographs acquired during the periodic surveys preceding the survey conducted on October 1st, 2005 by the SNET team, with the strong degassing phase (a) and (b) the incandescence of the central part of the fumaroles' area. c–f) Landsat 7 (ETM+ sensor) images, showing the location of the thermal anomalies around the summit crater area. The first clear thermal anomaly appeared on November 8th, 2004 (d), and rimmed the crater lake on the western side. In the July 20th, 2005 image, the anomaly was more relevant, and its shape had not changed significantly (e). The October 24th, 2005 (f) does not show any sign of thermal activity, and the fumaroles field previously identified, appear dismissed. We combined Band 7 (Mid infrared), Band 5 (Near infrared) and Band 4 (Near infrared) into the RGB.

Ana volcano was entering into a “seismic unrest” phase. Notably, both signals define a marked increasing trend with time, mainly highlighted by the records of long period (LP) daily rate until August 2004 (cf. Fig. 2a).

4.1.2. Phase Ib (September 21st, 2004 – July 7th, 2005)

On September 21st, 2004 the first genuine thermal alert (1.6 MW) was detected by the MIROVA system. This “thermal unrest” phase persisted for about one year and, since then, coexisted with the anomalous seismic activity (Fig. 2b). Since this first detection, the MODIS data define a nearly constant increase in the number and magnitude of thermal anomalies that, during the January–April period, was coupled with a relatively slight enhancement in tremor amplitude (Fig. 2b, c). High resolution Landsat (ETM+) images (see Fig. 3c–f), indicate that these MODIS derived thermal anomalies were originating from a high temperature and strong degassing fumaroles’ field (located on the western rim of the summit crater lake). In spite of the persistence of moderately high level of activity at the adjacent fumaroles (e.g. degassing), no significant anomalous signals were observed in the temperature of the water lake (Fig. 2d; Colvin, 2008; Olmos et al., 2007).

Periodic measurements of fumarolic temperature (between 14th and 18th June 2005) recorded a sudden increase, from 84 °C to 95 °C (Fig. 4), that was preceded by the Jun 15th, 2005 phreatic eruption. This event was characterized by intense gas emissions, moderate ejection of blocks and the deposition of a 1 mm thick ash layer at the northern sector of the volcano (SNET Informes Especiales, 2005a, b). This event did not produce immediate structural changes at the summit, although it was the first explosion during the analyzed unrest phase. Since then, we observe a general, marked increase at all the monitored parameters (Figs. 2 and 5) and we regard the June 15th explosion as a key episode, which promoted the connection between the magmatic hydrothermal system and the surface fumarolic field.

4.1.3. Phase Ic (July 8th, 2005 – August 30th, 2005)

The July–August 2005 period is characterized by a general growth of both LP and VT events as well as by the increased thermal flux (VRP), tremor amplitude (RSAM) and SO₂ degassing (Fig. 5). In particular, we fix the onset of this phase with the sharp increase in thermal activity, initially being higher than 10 MW (never observed before) and culminating, on August 27th, 2005 (at 04:05 UTC time), up to 31 MW.

Notably, between the August 24th and 30th, 2005, the SO₂ flux (4285 T/d), thermal flux (31 MW) and tremor amplitude (154 cts) reached peak values. Field surveys on August 29th, 2005 indicated that the fumaroles’ area was affected by incandescence (hot cracks; ~200 m²) and intense degassing activity (cf. Fig. 3b; SNET Informe Especial, 2005c).

By the end of August 2005, volcanic activity entered into a critical phase, when thermal, degassing and seismic parameters (RSAM) reached their peak values since the first signals of unrest. At that time, no physico chemical and thermal changes occurred at the crater lake, suggesting that its bottom was essentially sealed, and was not affected by the above perturbations. A similar phenomenon was observed by Casertano et al. (1987) at the Poás volcano during the winter of 1980; in this case also, there was an incandescence of the central dome with temperatures reaching 960 °C (preceded, four months prior, by intense seismicity) that did not affect the nearby water lake temperatures.

4.1.4. Phase Id (August 31st – September 30th, 2005)

During September 2005, LP and VT events showed a further increase with a maximum of 622 LP events/day, recorded on September 12th (Fig. 5a, b). Conversely, the radiative power, tremor amplitude and SO₂ flux followed a nearly coeval waning trend (Fig. 5c, d, e) likely related to a decrease in the activity of the fumaroles. The September 25th field thermal surveys did not show the existence of fresh magma at the surface. In turn, the water lake temperature increased, reaching its top value of 58 °C (Hernández et al., 2007; cf. Fig. 2d). Notably, the last satellite thermal detection (about 3 MW) occurred on September 26th, 2005, just five days before the main eruptive event of October 1st, 2005.

4.2. Phase II (October 1st, 2005): phreatomagmatic explosion

After about 500 days from the onset of seismic swarms, at 08:30 a.m. of October 1st, 2005 a VEI 3 phreatomagmatic eruption (Global Volcanism Program, 2005) affected the summit area of the Santa Ana volcano. This major event caused the emission of about 15,000 m³ of ash (Global Volcanism Program, 2005) associated with the release of 12 kT of SO₂ into the atmosphere (Carn et al., 2016) and the development of a 12 km high eruptive column (cf. Scolamacchia et al., 2010).

In the following days, heavy rainfalls, due to severe atmospheric perturbations associated with the arrival of hurricane Stan in the area,

Fig. 4. Santa Ana summit area with the location of the fumaroles’ temperature measurements (blue circles); inset shows the 14–18 June 2005 time-series of temperatures, collected automatically. The dotted line with the yellow star marks the occurrence of the phreatic explosion.

Fig. 5. Time series the main acquired parameters at the Santa Ana volcano during the September 2004 – October 2005 period. The dotted bars represent the limits of the recognized sub-phases, red line marks the October 1st, 2005 eruption and yellow star the June 15th, 2005 first phreatic eruption.

triggered several lahars and landslides onto the South East slope of the volcano which induced local authorities to evacuate about 5000 inhabitants (cf. [Global Volcanism Program, 2005](#); [Scolamacchia et al., 2010](#)). Moreover, the hot lahars damaged the vegetation of the summit area, up to 3–5 km distance from the hilltop. The ash fallout affected the western sector of the cone, including the villages of Los Naranjos, La Majada and Apaneca ([Olmos et al., 2007](#); [Scolamacchia et al., 2010](#)). As a whole, this event caused two deaths and the damage of about 1400 ha with a major impact on the local economy, essentially based on agriculture ([Global Volcanism Program, 2005](#)).

During this major phreatomagmatic explosion, the fumarolic area disappeared (cf. [Fig. 3f](#)) and the eruptive event drastically changed the morphology of the summit crater area ([Hernández et al., 2007](#)).

4.3. Phase III (October 2, 2005 – January 2008): crater lake activity

After the October 1, 2005 explosion, summit activity was characterized by the total absence of thermal anomalies, and by a general decrease in seismicity and SO_2 emissions which, however, were some how above background levels (cf. [Fig. 2](#)). Notably, the VEI 3 eruptive event was a prelude to the following crater lake's anomalous activity

(cf. [Rouwet et al., 2014](#)) that characterized the Santa Ana volcano for about 3 years, with several phreatic explosions, physico chemical changes and drastic temperature variations within the summit lake (cf. [Colvin et al., 2013](#)).

In this period, the crater lake suffered several phases of instability with marked evaporation cycles (not related to daily and seasonal behavior) and minor phreatic explosions ([Fig. 6](#)). Until April 2006, the lake underwent visible evaporation processes (i.e., bubbling), leading to the decline of about 30% of its volume on April 20, 2006 (with respect to the pre eruptive phase volume), coupled by changes in water coloration ([Fig. 6a, b, c](#)). Until September 2007, the crater lake cyclically suffered strong modifications, particularly during March–April, when the water lake reached temperatures above 50°C (max 67°C the March 13rd, 2007; cf. [Fig. 2d](#)). The occurrence of minor phreatic explosions (e.g. March 15th and April 27th) was accompanied by a drastic decrease of the lake size, which, in the following month, reached to about 4% of its original volume ([Fig. 6d, e, f](#)). Since the end of 2007, the lake has shown a nearly stable temperature (30°C on average) and has partially recovered its pre eruptive volume (cf. [Colvin et al., 2013](#)). Currently, no anomalous activity has been recorded at the Santa Ana Volcano (SNET, 2017).

5. Discussion

So far, we outlined the temporal evolution of the monitored parameters before and after the October 1, 2005 phreatomagmatic eruption. To proceed, we will be discussing these topics in the attempt to link the observed volcanic processes with the problems of forecasting of eruptions at the Santa Ana. In this perspective, unrest phases have been tentatively linked with the intensity of volcanic processes occurring before, during, and after the onset of the October 1, 2005 paroxysm, following the classification described by [Potter et al. \(2015\)](#).

5.1. The Santa Ana volcano: from seismic unrest to crater lake activity

The combined acquisition of ground and space based time series over a given volcanic area contributes to volcano surveillance and risk mitigation as well as to the better understanding of surface and deeper processes that drive the observed volcanic activity (cf. [Coppola et al., 2017](#); [Ripepe et al., 2015](#); [Valade et al., 2016](#)). The multiparametric dataset acquired at Santa Ana volcano, coupled with periodic surveys, give us the opportunity to reconstruct ([Fig. 7](#)) the migration of an undegassed magma batch toward the surface, as well as its effects on the hydrothermal system and the connected crater lake.

By analyzing the time evolution of the Santa Ana 2004–2005 activity, we link seismic unrest (VT swarms and the LP events) to the ascent of a magma batch (e.g. [McNutt, 2000](#); [Zobin et al., 2008](#); [Cannata et al., 2013](#)) that promoted crack propagation, substantial heat flow growth, and degassing (cf. [Chouet and Matoza, 2013](#); [Fig. 7a](#)).

This process induced an increase in thermal activity (i.e. rock crack incandescence within the fumaroles field), tremor amplitude and SO_2 flux ([Fig. 7b, c](#)). It is worth noting at this stage, that no physico chemical and thermal changes were observed (and/or recorded) within the crater lake, suggesting that it was still insulated (i.e., sealed) from the surroundings, whereas the fumarole field was affected by anomalous degassing.

The increase in water temperature within the lake ([Hernández et al., 2007](#)) was observed only on September 2005 (i.e., about one year after the beginning of the unrest) and was accompanied by a decrease in tremor amplitude, sulfur outgassing and space detected thermal anomalies (cf. [Figs. 2 and 7d](#)).

5.1.1. Magma hydrothermal system relationships

Particularly during *Phase Id* ([Figs. 5 and 7d](#)), seismic activity (VT and LP events) was high, and it is generally known that this scenario may precede explosive episodes, such as phreatic and phreatomagmatic

Fig. 6. A collection of photographs resuming the changes of Santa Ana crater lake, from November 2005 to May 2007. Frame 5e reports the phreatic blast of April 27th, 2007.

eruptions (e.g. Ruapehu; cf. Christenson and Wood, 1993; Christenson et al., 2010). Indeed, the major phreatomagmatic eruption occurred on October 1, 2005 (VEI 3) (Fig. 7e). Likely, during its onset, a direct interaction between the magma and the hydrothermal system occurred, opening the fracture system that was previously sealed. Since then, crater lake activity has been operative for the following three years (cf. Olmos et al., 2007; Colvin et al., 2013; see Fig. 7f). The occurrence of juvenile andesitic to rhyolitic glass fragments in the erupted materials support the idea of a near surface ascent of a magma body during the October 1st episode (cf. Scolamacchia et al., 2010).

The phenomena observed at Santa Ana are comparable with those occurring at Poás (Laguna Caliente) and Asosan (Yadamari) which also host a summit lake with nearby high temperature fumarolic fields (cf. Fischer et al., 2015; Shinohara et al., 2015).

However, it is worth analyzing the transition of hydrothermal activity from the fumarole field to the crater lake. This process is substantially accomplished during *Phase Id* (Figs. 5 and 7d). Fluid motion, associated with previous, vigorous degassing contributed to the progressive sealing the fractures of the hydrothermal sector comprised between the magma body and the fumaroles. This dynamic typically occurs in volcanic hydrothermal systems due to the sustained fluid flux as noticed by Olmos et al. (2007) and Rosas Carbajal et al. (2016). This process is usually accompanied by a pervasive “argillification” of the wall rock (e.g., Williams Jones et al., 2000; Finizola et al., 2004). The coupling of the above mechanisms are able to prevent both heat transfer and gas flux toward the surface, thus generating an overpressure below the self sealed horizon (Casadevall et al., 1981; Cigolini et al., 2005; Cigolini, 2010).

In our specific case, the increase in seismic activity (i.e., *Phase Ic d*; see Fig. 5) associated with the migration of the magma body, likely induced fracturing of the low permeable rock layer that typically underlay a crater lake (Colvin, 2008). In turn, the opening of the fracture system depressurized the stored magma that interacted with the water table, triggering the phreatomagmatic eruption (*Phase II*). The following period (*Phase III*), characterized by “peak/high level activity” of the crater lake (e.g., Rouwet et al., 2014), eventually associated with phreatic eruptions, is consistent with the above setting, when the fumaroles’ field is dismissed and the fluid flux is concentrated within the summit lake (cf. Tassi et al., 2009). Notably, a similar mechanism has

been recently suggested for the 2000–2008 activity at Poás volcano (Fischer et al., 2015).

Likewise, at the Santa Ana volcano, the gas release from magma may cause the partial or complete sealing of the fractures network below the fumaroles that, however, promote, due to the pressure, the disruption, and the fracturing of the rock layer below the lake. This scenario favored the interaction between the intruded magma body and the lake, as testified by the consequent setting c in the lake.

5.2. Timeline of the volcanic unrest

As recently reported (cf. Phillipson et al., 2013), the timeline of the events that occurred at the Santa Ana volcano can be considered a reference case for analyzing unrest levels on active volcanoes. In fact, the 2004–2005 scenario is overlapping the five level scale of Volcanic Unrest Index (V.U.I.) proposed by Potter et al. (2015), where each level was characterized by a peculiar observed and/or measured activity. In fact, we may notice that approaching the Oct 1, 2005 eruption, Santa Ana shifted from level 1 (Negligible) to level 4 (Heightened) during its unrest. In Fig. 8, we graphically reconstruct the link between the unrest level and the evolution of the events. The entering on an unrest state is typically heralded by seismic swarms, which is considered a long term (up to years) precursor of eruptions (cf. Phillipson et al., 2013; White and McCausland, 2015). At Santa Ana volcano, space based thermal anomalies had appeared more than one year prior (375 days) the October 1, 2005 explosion (Fig. 8). This is a striking novelty considering that, historically, the thermal anomalies have been substantially regarded as a short time precursor (8 days, on average; cf. Phillipson et al., 2013).

Although we likely consider the one year long Santa Ana thermal unrest a quasi unique case of long time high fumarolic activity capable to be detected by satellite observations, an additional and remarkable result is that the MIROVA algorithm was particularly efficient in identifying low thermal anomalies. We stress that during the Santa Ana unrest phase, the magma body was confined at depth, and the thermal anomalies were essentially due to high temperature magma related fluids ascending through hot cracks. Hence, as per the sporadic 2001–2002 recorded thermal anomalies (cf. Supplementary Material), no magma reached the surface. As a whole, such as at the Santa Ana volcano, an intense fumaroles’ activity may precede explosive eruption phases and/or

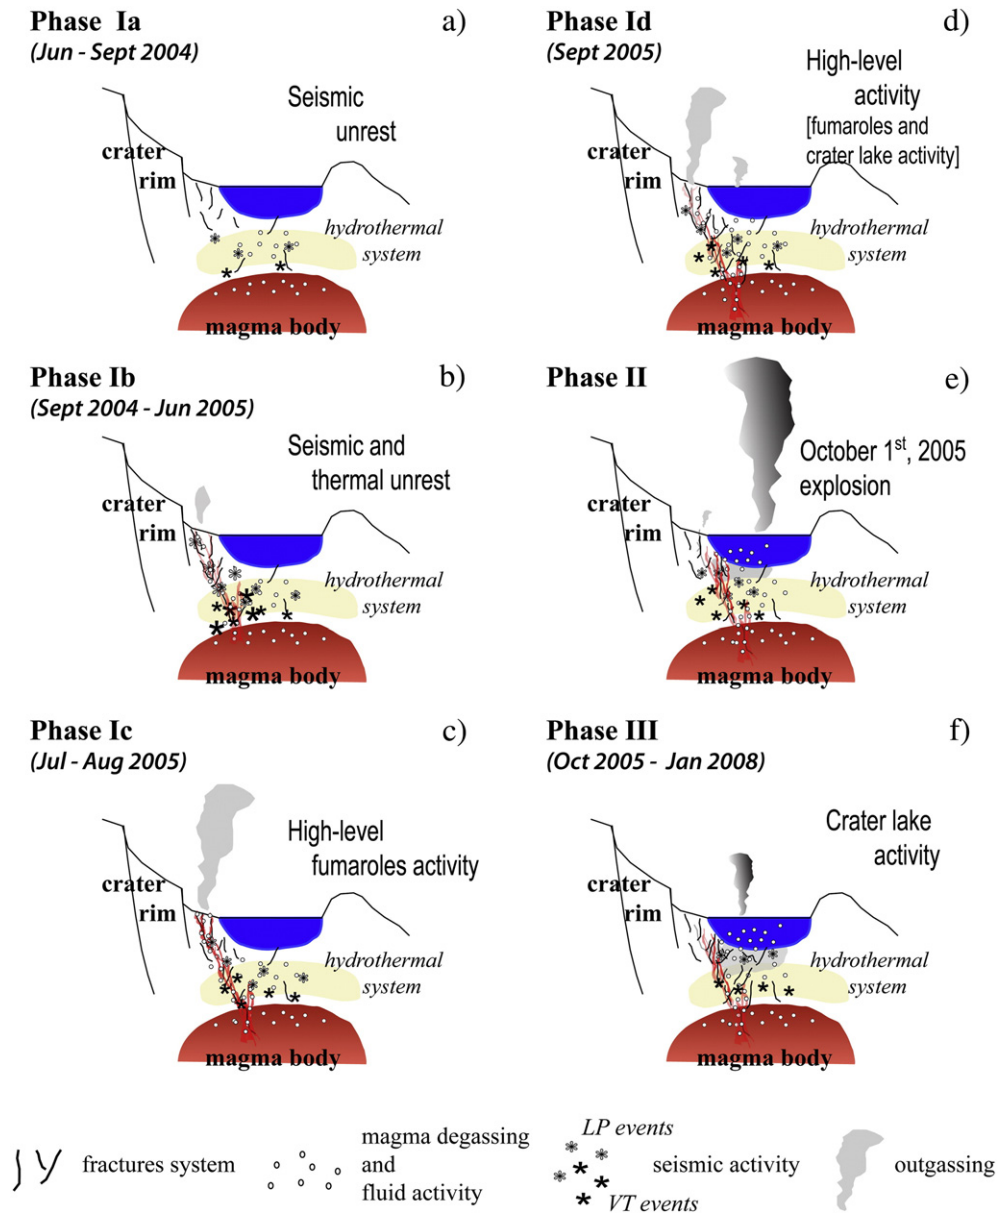

Fig. 7. Schematic model, representing the evolution of the shallow plumbing system of Santa Ana volcano, spanning from seismic unrest (June 2004) to the beginning of crater lake activity (October 2005). See text for details.

a lava dome extrusions (Connor et al., 1993; Taran et al., 1995; Hutchison et al., 2013), outlining the remarkable support of our space based measurements on the monitoring of active volcanoes.

6. Conclusions

The analysis of the MODIS infrared data over Santa Ana volcano reveals that the October 1, 2005 phreatomagmatic eruption has been preceded by one year long thermal anomalies associated with the high temperature fumaroles located on the side of the summit crater lake.

By combining satellite thermal data with the geophysical, geochemical and lake temperature measurements, we identified progressive levels of volcanic unrest preceding the main eruptive event. We linked this scenario with the upward migration of an undegassed magma batch promoting seismic, thermal and outgassing anomalies, which involved, at different stages, the fumarole field and, finally, the crater lake. Our results demonstrate the capability of the MIROVA system to track volcanic processes that may precede explosive eruptions and/or lava dome extrusions.

We suggest that the integration of satellite thermal data in a ground based monitoring network represents a strategic tool in volcano surveillance, aimed to forecast eruptions, and mitigate volcanic risk.
