1 **1. Introduction**

2 Marine apex predators, such as marine mammals, tunas, billfish and sharks, act as both
3 drivers of the ecosystems in which they live and sentinels of environmental health (Green
4 and Larson, 2016; Ramos and González-Solís, 2012). Due to their long lifespans and
5 position at the top of the food chain, they tend to exhibit high concentrations of persistent and
6 hydrophobic chemical contaminants in tissue *via* bioaccumulation and biomagnification
7 (Borgå et al., 2004; Kelly et al., 2007; Mackay and Fraser, 2000).

8 Contaminants that are persistent, bio-accumulative and toxic, such as persistent organic
9 pollutants (POPs), may inflict the greatest amount of damage on ecosystems (UNEP, 2001;
10 Green and Larson, 2016; Jepson and Law, 2016). POPs, which are essentially synthesized
11 by humans are characterized by their ability to travel long distances, resulting in their transfer
12 far from emission sources (Beyer et al., 2000; Brown and Wania, 2008; Corsolini et al.,
13 2014), mainly through atmospheric volatilization and condensation cycles referred to as
14 global distillation (Dachs et al., 2002; Wania and MacKay, 1996). POPs are hence
15 widespread in the environment; they occur in various matrices and regions around the world
16 (Dachs et al., 2002; Pozo et al., 2006; Reid et al., 2000) and as such are considered as
17 global pollutants (Pozo et al., 2006). POPs include well-studied polychlorinated biphenyls
18 (PCBs) and various organochlorine pesticides (OCPs), as well as other substances listed
19 more recently in the Stockholm Convention (UNEP, 2001), such as perfluorooctane sulfonate
20 (PFOS). Historically, OCPs, in particular hexachlorocyclohexane (HCH) and
21 dichlorodiphenyltrichloroethane (DDT), were synthesized in high quantities (Li, 1999; Li and
22 Macdonald, 2005). Although the production of legacy POPs has ceased in most countries,
23 contemporary inputs into the environment continue to originate from secondary sources such
24 as open burning, disposal of products containing PCBs, recycling of electric and electronic
25 devices or PCB-containing pigments used in household paints (Breivik et al., 2011; Grimm et
26 al., 2015), or from direct use, e.g. DDT against vectors of diseases (Qiu et al., 2005; van den

27 Berg et al., 2017). The ban on certain chemical substances has led to their replacement with
28 new substances, classified as contaminants of emerging concern (CECs). For example, the
29 ban on PFOS has led to the use of long-chain (> 7 carbon atoms) perfluorinated carboxylic
30 acids (PFCAs), found in increasing amounts in the environment (Wang et al., 2017). Oceans
31 are recognized as the main reservoirs of these compounds (Johansson et al., 2019). In this
32 context, both legacy POPs and CECs need to be studied in many oceanic regions, in
33 particular those remote from major sources of direct pollution, such as the southern Indian
34 Ocean (Corsolini et al., 2016; Hoydal et al., 2015; Roscales et al., 2016; Trumble et al.,
35 2012).

36 The tiger shark (*Galeocerdo cuvier*: Péron & Lesueur, 1822) and bull shark (*Carcharhinus*
37 *leucas*: Müller & Henle, 1839) are apex predators inhabiting both coastal and oceanic tropical
38 ecosystems (Compagno, 1984), where they play a major role (Heithaus et al., 2008). Both
39 species are generalist feeders that can forage on prey of aquatic or terrestrial origin (Cliff and
40 Dudley, 1991; Dicken et al., 2017; Trystram et al., 2017). More specifically, in Reunion Island
41 (RUN), an oceanic island in the Southwest Indian Ocean, these two sympatric species differ
42 in terms of prey and trophic habitat specialization (Le Croizier et al., 2020; Trystram et al.,
43 2017). Both species are characteristic of the marine fauna of RUN (Fricke et al., 2009) and
44 play a key role in the island's coastal ecosystem dynamics. However, no rigorous
45 assessment of their exposure to organic contaminants has so far been conducted, despite
46 the fact that they feed at high trophic levels, as do marine mammals (Jepson and Law,
47 2016), which are subject to excessively high concentrations of PCBs associated with long-
48 term population declines (Dirtu et al., 2016; Mwevura et al., 2010; Tanabe, 2002). Actually,
49 the contamination of marine ecosystems by organic contaminants in RUN has been the
50 subject of a very limited number of studies (Dirtu et al., 2016; Munsch et al., 2016), in
51 particular with regards to CECs. More generally, organic contaminant occurrence in large
52 carnivorous shark species has been poorly documented (Cagnazzi et al., 2019; Fisk et al.,
53 2002; Gelsleichter et al., 2005; Lee et al., 2015; Schlenk et al., 2005; Weijns et al., 2015),
54 despite the fact that most of these species are threatened with overexploitation and habitat

55 destruction on a global scale (Dulvy et al., 2017; Ferretti et al., 2010). Studying the
56 accumulation of toxic pollutants in large sharks in general, and in tiger and bull sharks in
57 particular, is therefore essential. In addition, sharks have been shown to offload significant
58 amounts of contaminants to their offspring, potentially resulting in female depuration (Lyons
59 and Adams, 2015). Maternal transfer of toxic substances bioaccumulated in mothers is of
60 particular concern, as i) it may represent a risk for offspring due to early-stage exposure; ii) it
61 contributes to the global organic contaminant cycle *via* maternal offloading and transfer to
62 offspring prior to other external exposure (Lyons and Adams, 2015; Mull et al., 2013). In
63 elasmobranchs, pregnant females transfer chemical contaminants to their offspring through
64 various pathways related to their reproductive strategy (oviparity, ovoviviparity, aplacental or
65 placental viviparity), which may in turn affect contaminant levels and profiles in offspring
66 (Cagnazzi et al., 2019; Lyons and Adams, 2015; Lyons and Lowe, 2013; Mull et al., 2013).
67 The bull shark is a viviparous species whose embryos are fed by direct maternal inputs *via* a
68 placental bond after absorption of yolk reserves, while in the ovoviviparous tiger shark,
69 embryonic development is solely ensured by a yolk, with additional nutritional inputs during
70 gestation (Castro et al., 2016). Both of these modes of gestation incur maternal transfer of
71 hydrophobic pollutants (Lyons and Adams, 2015; Mull et al., 2013; Olin et al., 2014; Weijs et
72 al., 2015). Our study aimed to characterize the contamination of tiger and bull sharks from
73 RUN by legacy POPs and CECs in order to identify contaminant sources and explore the
74 potential use of contaminants as trophic habitat tracers. The influence of biological
75 parameters (size as a proxy of age, sex, lipid content) on contaminant bioaccumulation and
76 maternal transfer were also studied. The presented data on the contamination of two top
77 predator sharks from the Indian Ocean could constitute an essential benchmark for further
78 studies.

2. Materials and methods

80 2.1. Sample collection

81 Tiger sharks (*Galeocerdo cuvier*, n = 21) and bull sharks (*Carcharhinus leucas*, n = 18) were
82 collected in 2018 and 2019 as part of a shark control program implemented following an
83 increase in shark attacks on the West coast of RUN (Lagabrielle et al., 2018). All individuals
84 were caught along the West coast of the island, where most nautical activities take place, at
85 depths between 10 m and 70 m (ca. 0.2 to 2 km from the shore) using bottom setlines and
86 SMART (shark management alert in real-time) drumlines (Guyomard et al. 2019) and were
87 dissected less than 36 h after capture. On the basis of demographic parameters for the two
88 species in RUN (Pirog et al., 2019a, 2020), the studied specimens included both mature and
89 immature individuals, including one 82 cm female bull shark specimen considered as
90 offspring of that year (referred to as “young-of-the-year” later in the text). Our sampling
91 strategy focused on a wide range of morphometrics for the purpose of studying organic
92 contaminant bioaccumulation as a function of individual size. Total mass (W in kg) and total
93 length (measured from the tip of the nose to the end of the tail, T_L in cm) were measured in
94 all studied individuals to the nearest gram and centimetre respectively, and sex was
95 determined through visual observation (presence/absence of claspers in males/females
96 respectively). In addition, all non-empty or regurgitated stomach contents were analysed to
97 describe diet. In order to assess shark physiological condition, the Fulton’s condition factor
98 (K) was calculated as follows:

$$K = 100 \times ((W \times 10^3) \times T_L^{-3})$$

100 whereby W is mass (kg) and T_L is total length (cm) (Gilliers et al., 2004).
101 Muscle was chosen as a good integrator of organic contaminants over time due to its slower
102 turnover rate compared to liver (Cullen et al., 2019). White muscle was collected between the
103 dorsal fins of adults. Embryos were also collected from one female of each species. A total of
104 eight embryos were collected from the bull shark mother and ten embryos from the tiger

105 shark mother. Whole dorsal muscle was taken and pooled from 2 individuals of same sex
106 and similar sizes to obtain a total of 4 pooled samples for tiger and bull sharks; two tiger
107 sharks embryos were also analysed individually. Shark embryos are good indicators of
108 maternal transfer of pollutants as they are not exposed to external food.

109 All samples were stored in amber glass vials at -20°C until further treatment. Prior to total
110 lipid content and organic contaminant analyses, the samples were homogenized using a
111 blender, freeze-dried for 72 h and finely ground using a MM200 ball mill (Retsch).

112 2.2. Total lipid content analysis

113 Extractable organic matter, used as a proxy for total lipid content (TLC), was determined with
114 0.5 g dry weight (dw) of sample extracted with a mixture of n-hexane and acetone (80/20
115 volume/volume [v/v]) using pressurized liquid extraction (PLE) at 100 °C under 10 MPa by
116 means of an ASE 350 (Dionex©) (Munsch et al., 2020). The extracts were evaporated to
117 dryness and TLC was determined gravimetrically and expressed in % of wet weight (ww).

118 2.3. Organic contaminant analysis

119 PCBs and OCPs were determined as described by Munsch et al., 2016. Briefly, 5-10 g of
120 samples were extracted by PLE with dichloromethane. Prior to extraction, ¹³C₁₂-labelled
121 compounds (18 PCBs, including 12 dioxin-like (dl-), 6 indicator (i-) PCBs, 5 DDT isomers,
122 aldrin, dieldrin, endrin, isodrin, α-, β-endosulfan and endosulfan-sulfate) were added to the
123 sample for internal standard calibration and quantification using the isotopic dilution method.
124 The extracts were successively purified using gel permeation chromatography, a silica and
125 alumina adsorption chromatography column and two-dimensional HPLC system with two
126 columns coupled in series. Four fractions were obtained (F1: non-coplanar PCBs and *p,p'*-
127 DDE, F2: coplanar PCBs, F3: OCPs, F4: remaining OCPs, treated with concentrated
128 sulphuric acid). Analyses were performed by gas chromatography coupled with high
129 resolution mass spectrometry (GC–HRMS) using a Hewlett-Packard 6890 gas
130 chromatograph fitted with an SGE HT-8 capillary column (50 m × 0.22 mm × 0.2 µm) and

coupled to an AutoSpec Ultima mass spectrometer (Waters Corp.). The samples were analysed for 30 PCBs ranging from trichlorinated to decachlorinated congeners, including the 12 dioxin-like (dl) -PCBs (CB-77, -81, -105, -114, -118, -123, -126, -156, -157, -167, -189), the 6 indicator (i)-PCBs (CB-28, -52, -101, -138, -153, -180) and various OCPs (*p,p'*-DDT, *o,p'*-DDT, *o,p'*-DDD, *p,p'*-DDD, *p,p'*-DDE, dieldrin, aldrin, isodrin, mirex and hexachlorobenzene -HCB). Compounds were quantified by isotopic dilution using the corresponding $^{13}\text{C}_{12}$ -labelled isomers (except mirex, quantified using ^{13}C *p,p'*-DDE) and internal standard method was used to quantify samples. Prior to injection, a solution containing $^{13}\text{C}_{12}$ -labeled CB-70, -111 and -170, d_8 -labeled *p,p'*-DDD and *o,p'*-DDT was added to the final purified extracts for signal correction. Perfluoroalkylated substances (PFASs) were determined according to Munsch et al., 2019. Briefly, one gram of a freeze-dried sample, to which an internal standard mixture of nine labelled compounds was added prior to agitation, was extracted using liquid-solid extraction with MeOH/KOH (0.01 M of KOH), purified onto two consecutive SPE cartridges (a WAX weak anion exchange stationary phase and an Envicarb charcoal stationary phase, evaporated to dryness and reconstituted in 200 μL of a mixture of MeOH:H₂O (50:50, v/v), to which PFOS $^{13}\text{C}_8$ was added. The following compounds were analysed, including five C₄- to C₁₀-perfluoroalkyl sulfonates (PFSAs) and nine C₆- to C₁₄ perfluorocarboxylic acids (PFCAs): perfluorobutane sulfonate (PFBS); perfluorohexane sulfonate (PFHxS); perfluoroheptane sulfonate (PFHpS); perfluoroctane sulfonate (PFOS); perfluorodecane sulfonate (PFDS); perfluorohexanoic acid (PFHxA); perfluoroheptanoic acid (PFHpA); perfluoroctanoic acid (PFOA); perfluorononanoic acid (PFNA); perfluorodecanoic acid (PFDA); perfluoroundecanoic acid (PFUnDA); perfluorododecanoic acid (PFDsDA); perfluorotridecanoic acid (PFTrDA) and perfluorotetradecanoic acid (PFTeDA). Targeted analytes were quantified using the corresponding isotope labelled standard, unless otherwise stated. The labelled standards were PFHxS $^{18}\text{O}_2$ (used to quantify PFBS and PFHxS), PFOS $^{13}\text{C}_4$ (used to quantify PFHpS, PFOS and PFDS), PFHxA $^{13}\text{C}_2$ (used to quantify PFHxA and PFHpA), PFOA $^{13}\text{C}_4$, PFNA $^{13}\text{C}_5$, PFDA $^{13}\text{C}_2$, PFUnDA $^{13}\text{C}_2$, PFDsDA $^{13}\text{C}_2$, and PFTeDA $^{13}\text{C}_2$ (used to quantify PFTrDA

159 and PFTeDA). PFOS $^{13}\text{C}_8$ was added to the purified extracts before injection and used as an
160 injection standard. Analysis was performed using an Acquity ultra-performance liquid
161 chromatograph (UPLC®, Waters Corp.) coupled to a triple quadrupole mass spectrometer
162 (Xevo® TQ-S micro, Waters Corp.) interfaced with a Z-sprayTM (Waters Corp.) electrospray
163 ionization source. UPLC separation was achieved using an Acquity UPLC BEH C18
164 reversed-phase column (50 mm x 2.1 mm; 1.7 μm particle size) eluted with ammonium
165 acetate in water (20 mM) (A) and methanol (B).

166 2.4. QA/QC

167 Analyses were conducted under fume hoods with positive pressure in a low-dust laboratory
168 to minimize external and cross-contamination. For each series of 10 samples for PCBs and
169 OCPs and of 15-20 samples for PFASs, one in-house quality control (QC) sample and one
170 procedural blank were processed.

171 The QC for PCBs and OCPs was prepared from fish muscle spiked with OCPs at 0.1 - 0.2 ng
172 g $^{-1}$ dw, while method performances were assessed using PCBs already present in the
173 sample. For PFASs, the QC was prepared using commercially-purchased whole mussel
174 tissue spiked with the targeted compounds at 0.2 to 0.3 ng g $^{-1}$ dw. Trueness, calculated as
175 the relative bias compared to targeted values, was 0.3 - 23% for PCBs, 0.4 - 23% for OCPs
176 and 5 - 33% for PFASs.

177 Procedural blanks, incorporating all steps of the protocol, were analysed with each series of
178 12 samples ($n = 4$). Contaminants detected in more than 50% of the procedural blanks
179 included various PCB congeners (CB-28, -31, -44, -49, -52, -66, -77, -87, -101, -105, -110, -
180 118, -132, -138, -149, -151, -153, -156, -170, -180, -183 and -187), HCB and dieldrin for
181 OCPs, and PFHxA, PFHpA, PFOA, PFNA, PFTrDA and PFTeDA for PFASs. Concentrations
182 in blanks, calculated with the extracted sample masses, were 0.22 - 3.2 pg g $^{-1}$ ww for PCBs,
183 1.9 - 26.8 pg g $^{-1}$ ww for OCPs and 1.4 - 37.7 pg g $^{-1}$ ww for PFASs. Concentrations in samples
184 were corrected using the blank value of each sample batch. The recovery ($n = 49$) of each
185 labelled compound ranged from $67 \pm 8\%$ (CB-52) to $85 \pm 16\%$ (CB-167) for PCBs, $42 \pm 14\%$

186 (α -endosulfan) to $115 \pm 22\%$ (dieldrin) for OCPs and $38 \pm 10\%$ (PFTeDA) to $85 \pm 10\%$
187 (PFHxA) for PFASs.

188 Limits of quantification (LOQs) were calculated for each target compound in each sample
189 using a signal-to-noise ratio of 3 (peak-to-peak) on the less intensive raw data signal
190 (qualifier ion) (Wenzl et al., 2016), taking into account injection volume, the volume of
191 concentrated extract prior to injection and extracted sample weight. LOQs ranged from 0.02
192 pg g^{-1} ww to 1.36 pg g^{-1} ww for PCBs, 0.1 pg g^{-1} ww to 27.4 pg g^{-1} ww for OCPs and 0.2 pg g^{-1}
193 pg g^{-1} ww to 19.0 pg g^{-1} ww for PFASs.

194 **2.5. Statistical analysis**

195 In view of the small number of studied individuals and non-homogeneous nature of dataset
196 variances, statistical analyses were conducted using non-parametric tests. Comparisons of
197 mean contaminant concentrations between species and between sexes of each species
198 were conducted using the Wilcoxon-Mann-Whitney test. The correlation between biological
199 parameters (size, mass, % lipids and K index) and organic contaminant concentrations was
200 assessed with the Spearman rank test. POP profiles were investigated using the Mann-
201 Whitney test and a standardized Principal Component Analysis (PCA) was additionally
202 performed using Euclidean distances for PCBs.

203 The data were analysed with R software (version 3.4.4). Mean comparisons and correlation
204 tests were conducted with the stat and Hmisc packages (Hollander et al., 2013). PCAs were
205 performed using the FactorMiner package (Husson et al., 2017).

206 **3. Results and discussion**

207 **3.1. Biological parameters**

208 Free swimming bull sharks ranged from 82 cm to 327 cm in size; tiger sharks ranged from
209 157 cm to 387 cm in size (Table 1). Embryos pertaining to each species were similar in size /
210 mass, but significant differences were found between the two species, i.e. $33 \pm 1 \text{ cm} / 0.12 \pm$

211 0.01 kg and 63 ± 1 cm / 1.7 ± 0.1 kg in tiger and bull sharks, respectively. Embryo sizes
212 corresponded to embryo ages of ca. 6 months and 10 months for tiger and bull sharks,
213 respectively (Pirog et al., 2019a, 2020; Whitney and Crow, 2007), i.e. at the third of total
214 gestation time for tiger shark (Pirog et al., 2020) and at the end of gestation for bull shark
215 (Pirog et al., 2019).

216 As no significant differences were found in any of the four biological parameters (T_L , W, K,
217 TLC) across sexes from either species, both sexes were considered together for
218 morphometric and lipid content comparison between species. Tiger sharks showed a similar
219 average total length and body mass to bull sharks. However, tiger shark maximum size (387
220 cm versus 327 cm) and mass (402 kg versus 299 kg) exceeded that of bull sharks. Fulton's
221 condition factor mean value was 0.7 times lower in tiger sharks versus bull sharks ($p = 5.10^{-7}$),
222 while TLCs were not significantly different between both species. K is often used as a
223 global indicator of habitat quality or food availability and a positive correlation with lipid
224 content has previously been described in juvenile white sharks (*Carcharodon carcharias*)
225 (Logan et al., 2018). The absence of correlation between K and TLCs in the studied species
226 (tiger sharks: $p = 0.45$; bull sharks: $p = 0.12$) may be due to age (large juveniles and adults)
227 or differences in the physiology and dynamics of lipid storage in the two species.

228 Fish, cephalopods, birds and unidentified remains were found in the non-empty stomachs of
229 bull sharks (64%) and tiger sharks (45%). These observations are coherent with data
230 previously reported by Trystram et al. (2017) and confirm a dominant piscivorous dietary
231 habit for both species, with tiger sharks exhibiting a more generalist foraging behaviour than
232 bull sharks.

233 3.2. Influence of biological parameters on organic contaminant bioaccumulation
234 Concentrations of the various families of studied organic contaminants in tiger and bull
235 sharks are presented in Table 2. Detailed results per individual compound are given in Table
236 S1.

237 The highest contaminant concentrations were found in tiger shark embryos, with the
238 exception of PFOS. In adults, OCPs were predominant in tiger sharks, followed by PCBs and
239 PFASs, while in bull sharks, concentrations ranked in the following order PCBs > OCPs >
240 PFASs. All concentrations were low in the young-of-the-year bull shark.

241

242 3.2.1. Chlorinated POPs

243 TLCs were not correlated with concentrations of the different contaminant families in either
244 species (whether only mature individuals were considered or not), indicating that TLC had a
245 limited influence on chlorinated POP bioaccumulation in white muscle. Chlorinated POP
246 concentrations were therefore primarily compared on a ww basis.

247 Each PCB congener was quantified in over 60% of shark samples, with the exception of CB-
248 31 and -209, which were detected in 45% of bull shark samples and CB-28, -31, -44 and -49,
249 which were detected in 15%, 15%, 40% and 40% of tiger shark samples, respectively.
250 Among OCPs, the 5 isomers of DDT, mirex and dieldrin were detected in over 90% of
251 samples from both species; endrin was detected in 50% and 75% of bull shark and tiger
252 shark samples, respectively. Contamination levels in adults ranged from 104 to 9885 pg g⁻¹
253 ww for Σ 30 PCBs, 50 to 2473 pg g⁻¹ ww for Σ DDTs, 3 to 1562 pg g⁻¹ ww for mirex and 6 to
254 49 pg g⁻¹ ww for the sum of dieldrin-endrine (Figure 1). A high inter-individual variability in
255 contamination levels was observed in both species probably due to the generalist foraging
256 behaviour of the two species (Trystram et al. 2017) that lead to a high variety of ingested
257 prey with potential different degrees of contamination. Besides, a wide range of sizes / ages
258 were considered, hence enhancing contamination variability. Organochlorinated compound
259 mean concentrations, on a ww basis, were 3 times higher in male than in female bull sharks
260 (Figure 1), although differences were not statistically significant for PCBs ($p = 0.03$ and 0.06
261 for OCPs and PCBs respectively) due to the high variability of contamination levels across
262 individuals (OCP concentrations were 1455.5 ± 1359.7 pg g⁻¹ ww in males and 419.6 ± 388.5
263 pg g⁻¹ ww in females; PCB concentrations were 4602.7 ± 4146.1 pg g⁻¹ ww in males and

1502.8 ± 1331.7 pg g⁻¹ ww in females). When normalized to lipid content, these concentrations were significantly higher in males for both OCPs and PCBs ($p = 0.006$ for OCPs and $p = 0.024$ for PCBs): 243.7 ± 189.9 ng g⁻¹ lw versus 68.4 ± 59.3 ng g⁻¹ lw in females for OCPs and 745.7 ± 606.0 ng g⁻¹ lw in males versus 261.9 ± 240.0 ng g⁻¹ in females for PCBs. Conversely, PCB and OCP concentrations were similar ($p = 0.35$) in both sexes in tiger sharks: OCP concentrations were 756.6 ± 756.5 pg g⁻¹ ww in males and 1268.4 ± 1066.1 pg g⁻¹ ww in females; PCB concentrations were 298.6 ± 155.0 pg g⁻¹ ww in males and 375.4 ± 348.1 pg g⁻¹ ww in females. When normalized to lipid content, these concentrations were 114.7 ± 105.6 ng g⁻¹ lw in males versus 208.0 ± 173.5 ng g⁻¹ lw in females for OCPs and 43.4 ± 17.3.0 ng g⁻¹ lw in males versus 59.0 ± 49.0 ng g⁻¹ lw in females for PCBs ($p = 0.17$ and $p = 0.76$ respectively). Differences in contamination levels between sexes may be caused by various factors such as reproductive loss, growth rate or diet (Larsson et al., 1993; Madenjian et al., 2010; Ng and Gray, 2009; Rypel et al., 2007). No sex-related dietary differences have been reported between the two species (Trystram et al., 2017); moreover, males have a higher growth rate than females (Cruz-Martínez et al., 2004; Kneebone et al., 2008). Neither of these factors would lead to the differences observed in contaminant accumulation in male and female bull sharks. The lack of sex-related influences on POP contamination in tiger sharks could indicate that reproduction has less impact on hydrophobic pollutant concentrations in ovoviparous female tiger sharks versus viviparous female bull sharks. The results suggest that the ovoviparous mode of gestation induces less decontamination in female shark muscle than viviparity. Actually, the continuous supply of nutrients during bull shark gestation could result in higher maternal contaminant offloading in comparison to egg-forming species such as tiger sharks (Castro et al., 2016). However, further investigations would be needed in order to confirm this hypothesis.

No significant differences in DDT concentrations were found between the two species (bull shark: 584 ± 648 pg g⁻¹ ww; tiger shark: 585 ± 580 pg g⁻¹ ww, $p = 0.9$), while PCB mean concentrations were 7 times higher in bull sharks (2597 ± 2968 pg g⁻¹ ww) than in tiger sharks (339 ± 270 pg g⁻¹ ww; $p = 10^{-6}$). The higher PCB contamination levels found in bull

sharks, combined with their more coastal habitat in RUN (Trystram et al., 2017), indicates exposure of these coastal environments to more significant PCB sources. Conversely, the similar levels of DDT accumulation found in both species suggests similar sources in both coastal (bull sharks) and offshore (tiger sharks) feeding habitats. Among OCPs, mirex concentrations were 2.5 times higher in tiger sharks than in bull sharks (tiger shark: 403 ± 431 pg g⁻¹ ww; bull shark: 180 ± 334 pg g⁻¹ ww, p = 0.028), while dieldrin concentrations were 1.5 times higher in tiger sharks than in bull sharks (tiger shark: 36 ± 14 pg g⁻¹ ww; bull shark: 24 ± 14 pg g⁻¹ ww, p = 0.016). As tiger sharks migrate long distances across the Indian Ocean (Pirog et al., 2019a), these differences suggest that certain insecticides, such as mirex and dieldrin, may be subject to different patterns of use on the Indian Ocean scale, despite the fact that these compounds have been banned in most countries. Although mirex has been detected in air and various matrices in the Indian Ocean, no specific source has been clearly identified (Bouwman et al., 2012; Qiu et al., 2020; Srimurali et al., 2015), while dieldrin may still be in use in Kenya (Barasa et al., 2008).

Only PCBs were significantly correlated to individual size in bull sharks (p = 0.038), while PCB, DDT and mirex concentrations showed positive correlations with tiger shark size (p = 0.0081, 0.00016 and 0.001 respectively). Contaminant accumulation over fish lifetime reflects a combination of various factors, such as fish growth rate, contaminant accumulation and elimination rates, and reproduction. In sharks, previously-reported results showed species-related relationships between contaminant accumulation and size (Lyons et al., 2019).

3.2.2. PFASs

Among the analysed PFASs, PFUnDA, PFTrDA and PFTeDA were more frequently detected in both species (95 - 100% of the samples), followed by PFDoDA (79%), PFNA (69%) and PFDA (59%). PFOS was above LOQs in 83% of bull sharks and only 24% of tiger sharks due to the low concentrations encountered. Other PFASs were below LOQs in all samples. Overall, PFOS concentrations above LOQs were in the 6.0 - 148.0 pg g⁻¹ ww range (mean of

319 $31.9 \pm 34.1 \text{ pg g}^{-1}$ ww, one male bull shark exhibiting a higher concentration of 555 pg g^{-1} ww
320 was excluded), while \sum PFCA concentrations were in the $69.0 - 353.5 \text{ pg g}^{-1}$ ww range, with
321 mean concentrations of $135.0 \pm 38.2 \text{ pg g}^{-1}$ ww in tiger sharks and $212.0 \pm 97.8 \text{ pg g}^{-1}$ ww in
322 bull sharks.

323 PFOS and \sum PFCA concentrations were not statistically different between sexes in either
324 species ($p = 0.12$ and 0.24 respectively for bull shark; PFOS not tested for tiger sharks and p
325 = 0.39 for \sum PFCAs). Unlike organochlorine compounds, PFASs did not show higher
326 concentrations in male bull sharks ($p = 0.32$); this could indicate that female contamination by
327 these compounds is less influenced by reproduction and mode of gestation versus PCBs and
328 OCPs. PFAS concentrations were significantly higher in bull sharks versus tiger sharks and
329 differences were significant for each individual compound ($p = 0.00051$ to 0.02), with the
330 exception of PFNA and PFTDA ($p = 0.051$ and 1 respectively). The higher PFAS levels
331 found in bull sharks suggest that their sources may be local rather than distant. High inter-
332 individual variability was observed (a factor of 5 between minimum and maximum PFAS
333 concentrations), as expected in view of the wide range of sizes / ages. However, no
334 significant correlation was found between PFAS concentrations and fish sizes in the two
335 species.

336 3.3. Contaminant profiles and ratios as tracers of contamination sources

337 No differences in PCB, DDT and PFAS profiles were found between sexes in either species,
338 suggesting that they share similar trophic habitats, as hypothesised by Trystram et al.,
339 (2017). Both sexes were thus examined together.

340 3.3.1. PCBs

341 PCBs can be classified according to the number and position of chlorine atoms, which affect
342 their hydrophobicity (Hawker and Connell, 1988) and propensity to be metabolized. Chlorine
343 atom position defines five structure-activity groups (SAGs), characterizing congener
344 metabolism capability (Boon et al., 1997; Yunker et al., 2011). Groups I and II are not

metabolized, group III is metabolized in some mammals but not in fish, and groups IV and V are metabolized in some fish (Buckman et al., 2007).

To assess contamination profiles, a standard PCA (Figure 2) was performed on all samples except the young-of-the-year bull shark, which was included for information purposes only (additional individual). In this analysis, the two first components representing 90.9% of total variance were used according to the Kaiser criterion (component eigenvalue > 1, Figure 2). Additional variables were groups poorly-represented in the factorial plan of the first two components (inertia of the variable in a component < mean inertia of that component). PCB congeners predominating in bull sharks were higher chlorinated (7 - 8 chlorine atoms) and non-metabolizable (SAG I), while tiger sharks were characterized by a higher variability in their profiles (Figure 2), corresponding to a higher diversity of tiger shark prey in RUN (Trystram et al., 2017). Univariate analyses confirmed that the relative abundance of these compounds differed significantly between the two species ($p = 0.00064$ and $p = 0.012$ for 7 and 8 chlorine PCBs respectively). The PCB contamination profile of the young-of-the-year bull shark was completely different to that of the other bull shark individuals.

PCBs exhibited a contamination profile dominated by higher chlorinated and non-metabolizable congeners in bull sharks. As the heavier congeners are less mobile and bind to organic matter near the coast, leading to preferential accumulation of these compounds in food webs close to their sources (Salvadó et al., 2013), bull sharks would appear to be more highly-impacted by local, coastal PCB sources. This surprising result, in view of the island's low level of industrialization, is corroborated by the study of Dírtu et al. (2016), which showed higher PCB levels in coastal Indo-Pacific bottlenose dolphins (*Tursiops aduncus*) than in spinner dolphins (*Stenella longirostris*) living further offshore in RUN. Conversely, tiger sharks were predominantly impacted by lower chlorinated PCBs, which can be transported further offshore.

370 3.3.2. DDTs

371 DDT profiles were dominated by *p,p'*-DDE followed by *o,p'*-DDT in tiger sharks and by *p,p'*-
372 DDT in bull sharks (Figure 3). Bull sharks showed significantly higher *p,p'*-DDE contributions
373 than tiger sharks ($97 \pm 3\% > 92 \pm 5\%$; $p = 9.4 \cdot 10^{-6}$).

374 The relative proportions of *p,p'*-DDE were higher than those reported in other high trophic
375 level predators in RUN by Munsch et al. (2016) and Dirtu et al. (2016). The ratio of (*p,p'*-
376 DDE + *p,p'*-DDD) / \sum DDTs concentrations, which is an indicator of *p,p'*-DDT degradation in
377 the environment, was not significantly different in the two species (0.95 ± 0.04 on average, p
378 = 0.88) and indicated that DDT sources in the studied sharks were old (Suárez et al., 2013).
379 The *o,p'*-DDT / *p,p'*-DDT concentration ratio, providing information on the source of DDT
380 contamination, showed values above 0.34 in both species, suggesting that dicofol may be a
381 contributor to contamination (Suárez et al., 2013). This ratio was significantly higher in tiger
382 sharks than in bull sharks ($2.19 \pm 2.17 > 0.55 \pm 0.52$; $p = 0.00034$), possibly indicating a
383 dicofol source outside RUN contaminating the Indian Ocean.

384 3.3.3. OCP / PCB concentration ratios

385 Various organic contaminant ratios, when used in combination with data on trophic habitats,
386 can be used to trace the trophic origin of contamination. The \sum OCP / \sum PCB concentration
387 ratio has been commonly-used in various species to provide an initial evaluation of industrial
388 or agricultural sources (Munsch et al., 2016; Storelli et al., 2006; Suárez et al., 2013). This
389 ratio differed significantly in the two species, i.e. 0.37 ± 0.24 in bull sharks and 2.93 ± 1.96
390 ($p = 6.3 \cdot 10^{-10}$) in tiger sharks, indicating that contamination profiles were dominated by
391 pollutants of different origin (industrial in bull sharks, pesticides in tiger sharks). Genetic
392 population and trophic ecology studies in RUN have shown that tiger sharks have an
393 offshore habitat and can navigate throughout the Indian Ocean basin (Pirog et al., 2019b;
394 Trystram et al., 2017). Conversely, bull sharks live in coastal environments, although some
395 individuals engage in wide scale movements in the Southwest Indian Ocean (Daly et al.,

396 2014; Lea et al., 2015; Pirog et al., 2019c; Trystram et al., 2017). In addition, the two species
397 feed on different prey in RUN. These information on the trophic habits of the two species
398 suggest that the coastal prey of bull sharks could be more highly-impacted by PCBs,
399 although the sources and the physicochemical dynamics of these pollutants in the tissues of
400 the two species could be an alternative explanation to the observed differences.
401 Concentration ratios were positively correlated with tiger shark size ($\rho = 0.60$; $p = 0.0073$)
402 suggesting changes in contamination sources according to age. Similarly, this could either be
403 due to movements throughout the Indian Ocean or to physiology-related changes.

404

405 3.3.4. PFASs

406 Concentrations of \sum PFCAs, including long-chain compounds ($C \geq 8$), were higher than PFOS
407 concentrations (on average by a factor of 11 and 17 in bull and tiger sharks, respectively) in
408 all samples (the above-mentioned male bull shark outlier excluded), consistent with the
409 higher bioaccumulative abilities of these compounds versus their short-chain counterparts
410 (Kelly et al., 2009; Martin et al., 2003; Pan et al., 2014). More specifically, PFCA profiles
411 showed a predominance of odd-chain length compounds (PFTrDA and PFUnDA) versus
412 even-chain (PFDA, PFDoDA and PFTeDA) (Figure 4), as previously observed in fish (Martin
413 et al., 2003; Sturm and Ahrens, 2010), including in the Indian Ocean (Munsch et al., 2020).
414 Their presence has been partially explained by the degradation of fluorotelomer alcohols
415 (FTOHs) (Ellis et al., 2004; Martin et al., 2004). PFUnDA and other long-chain PFCAs could
416 originate from the degradation of 10:2 FTOH (Hart et al., 2008). Odd-chain PFCAs such as
417 PFUnDA and PFTrDA have also been reported as impurities in PFNA resulting from the
418 oxidation of fluorotelomer olefins (Prevedouros et al., 2006; Rotander et al., 2012).
419 Tiger shark and bull shark long-chain PFCA profiles differed, with higher proportions of odd-
420 chain PFCAs in tiger sharks ($80 \pm 9\%$) versus bull sharks ($66 \pm 13\%$; $p = 0.00094$),
421 suggesting that dietary differences could result in different contamination patterns.

422 3.4. Maternal transfer

423 3.4.1. Contamination levels

424 In both species, organic contaminant concentrations showed low variability between embryo
425 pools (6 - 19% relative standard deviation for the various contaminant families within each
426 species), consistent with the fact that they originated from the same female, were of the
427 same age and were all exposed to similar contaminant sources (ie, yolk sac or placental
428 bond), with no external exposure.

429 In bull shark embryos, concentrations (in ww) were 4 to 25 times lower than those of their
430 mother for all chlorinated compounds except dieldrin (ratio mother / embryos of 1) (Table 3).

431 When normalized to TLC, embryo contaminations were 6 to 35 times lower than those of
432 their mother. Among perfluorinated compounds, PFCAs showed higher concentrations in the
433 mother, while PFOS was 3 times more concentrated in embryos. These results demonstrate
434 that lipophilic and amphiphilic molecules are not transmitted to embryos in the same manner,
435 indicating that molecule physico-chemical properties and affinity with major biological
436 macromolecules are determining parameters in the maternal transfer of organic
437 contaminants in bull sharks. Conversely, concentrations of all chlorinated compounds and
438 PFCAs expressed in ww (Table 3) were 2 to 7 times (and 3 times in lw) higher in tiger shark
439 embryos than in the mother, while PFOS was not detected in the mother and in 33% of
440 embryos only. In tiger sharks, embryonic development is ensured by a yolk sac and a high
441 energy uterine fluid (named the embryotrophe), as no placental connection exists (Castro et
442 al., 2016). The differences in modes of gestation and mean TLCs in embryos between the
443 two species (TLCs in tiger shark embryos were 2 times higher than in bull shark embryos (p
444 < 0.001)) could partly explain the fact that tiger shark embryos were exposed to higher levels
445 of lipophilic contaminants than bull shark embryos. However, further investigations of
446 embryos of both species at different stages of gestation would be necessary as both
447 embryos differed in their embryonic stage.

448 In bull sharks, a significant negative linear regression between the octanol / water partition
449 coefficient ($\log K_{ow}$; Hawker and Connell, 1988; Shen and Wania, 2005) and \log_{10} -
450 transformed ratio between the average concentration of organochlorinated compounds in
451 embryos versus the mother (i.e. the partition ratio), both normalized to lipid content, was
452 observed ($r = -0.85$, $p = 0.0005$, Figure 5A). Conversely, no significant relationship was found
453 in tiger sharks (Figure 5B). These results show that the maternal transfer of
454 organochlorinated compounds in viviparous sharks depends on molecule hydrophobicity. As
455 shown previously by Lyons and Adams (2015) in another placental shark species, our results
456 show that the most hydrophobic molecules were less transferred to the muscle of bull shark
457 embryos than the low hydrophobic ones. On the opposite, tiger shark embryo contamination
458 relative to their mother was not dependent on the molecule hydrophobicity (Figure 5B).
459 PFOS showed a higher partition ratio than PFCAs (0.45 for PFOS versus -0.17 ± 0.08 for
460 PFCAs) and PFCA partition ratios were negatively-correlated with the number of carbon
461 atoms ($\rho = -0.9$; $p = 0.016$) in bull sharks. All PFASs were detected in tiger shark embryos,
462 while in the mother, only PFUnDA and PFTrDA (partition ratio 1.29 and 1.19, respectively)
463 were detected, suggesting that PFASs were efficiently transferred to offspring. The
464 differences observed between the two species could be related to the biochemical
465 composition of tiger shark eggs versus exchanges driven by the placental bond of bull
466 sharks.

467

468 3.4.2. Contamination profiles

469 PCB profiles were similar in the tiger shark mother and embryos (Figure 2), while higher
470 relative concentrations of *p,p'*-DDE were observed in the mother (mother: 95%; embryos: 86
471 $\pm 0.5\%$; Figure 6A). Conversely, hexachlorinated congeners belonging to SAG III were less-
472 prevalent in the bull shark mother than in embryos (Figure 2), while similar DDT profiles were
473 observed (Figure 6A). The (*p,p'*-DDE + *p,p'*-DDD) / *p,p'*-DDT ratio was respectively 2 and 4
474 times higher in bull and tiger shark mothers than in their embryos, suggesting that DDT

475 transfer and accumulation in embryo muscle was isomer-specific. Similar PFAS profiles were
476 found in the bull shark mother and embryos, with the exception of PFOS, which showed
477 higher relative concentrations in embryos (9% in the mother and $31 \pm 4\%$ in her embryos;
478 Figure 6B). Only PFUnDA and PFTrDA were detected in the tiger shark mother, whereas
479 PFASs were detected in 100% of embryos, with the exception of PFOS and PFDoDA
480 detected in 33% and 83% of embryos, respectively. Our results show that the different
481 molecule families have different fates in the two studied species, suggesting that pollutant
482 family and mode of gestation (known to be different in the two species) are important factors
483 in the maternal transfer of organic contaminants.

484 3.5. Organic contaminant levels in sharks from Reunion Island versus worldwide levels

485 Large inter-individual variations in organic contaminant concentrations in sharks have been
486 found in previous studies worldwide (Table S2 and S3). Various factors, such as size, sex
487 and lipid levels of studied individuals, which are not always reported, the number of
488 compounds considered, the decrease in legacy POP concentrations and potential increase in
489 CECs over time (Tanabe and Ramu, 2012) could explain these variations.

490 Sharks sampled in various locations in the Southern Hemisphere have shown PCB
491 concentrations between 2 and 100 times higher than sharks from RUN (Cagnazzi et al.,
492 2019; Marsili et al., 2016). A pregnant bull shark and blacktip reef sharks (*Carcharhinus*
493 *melanopterus*) sampled in Australia and on the east coast of South Africa showed
494 concentrations similar to those of RUN bull sharks, but 10 times lower than those of tigers
495 sharks (Beaudry, 2014; Cagnazzi et al., 2019). PCB and DDT concentrations reported in
496 another top predator species (albacore tuna *Thunnus alalunga*) from the coast of South
497 Africa were lower than those found in RUN due to higher industrialization and urbanization in
498 South Africa (Dirtu et al., 2016; Munsch et al., 2016; Mwevura et al., 2010). DDT
499 concentrations were 5 to 100 times higher in sharks from the Southern Hemisphere oceans
500 than RUN (Beaudry, 2014; Cagnazzi et al., 2019; Marsili et al., 2016; Schlenk et al., 2005).
501 POP concentrations were therefore globally lower in individuals sampled in RUN versus

502 other locations in the Southern Hemisphere, probably associated with the island's low
503 urbanization and industrialization and its remote oceanic position far from landmasses.
504 High industrialization and urbanization in many areas of the Northern Hemisphere have
505 fostered major sources of POPs, leading in turn to higher concentrations in Northern
506 Hemisphere biota versus the Southern Hemisphere (Aguilar et al., 2002). Indeed, this is
507 clearly reflected in PCBs (Table S2) and, to a lesser extent, in DDTs (Table S3), indicating
508 that these banned compounds are still used in some countries in the Southern Hemisphere,
509 probably for mosquito control (van den Berg et al., 2017). Sharks caught in the Northern
510 Hemisphere showed 10 to 1000 times higher PCB concentrations than sharks caught in
511 RUN, with the exception of individuals caught near Portugal and in the Northeast Pacific
512 Ocean, which showed similar concentrations to bull sharks from RUN (Alves et al., 2016;
513 Boldroccchi et al., 2020; Cullen et al., 2019; Johnson-Restrepo et al., 2005; Lee et al., 2015;
514 Storelli et al., 2003). Mean DDT concentrations in RUN sharks were similar to those in
515 various shark species caught in the Northeast Pacific Ocean, with the exception of oceanic
516 whitetip sharks (*Carcharhinus longimanus*), characterised by 100-fold lower DDT
517 concentrations (Table S3; Lee et al., 2015). In contrast, RUN sharks showed 100 times lower
518 DDT concentrations than those of whale sharks (*Rhincodon typus*) from the Red Sea,
519 associated with the contemporary use of DDT in Djibouti (Boldroccchi et al., 2020), indicating
520 that DDT concentrations are strongly influenced by local sources and can therefore vary
521 greatly from one ocean basin to another. Mirex concentrations in the muscle of bonnethead
522 sharks (*Sphyrna tiburo*) from Florida were below LOQ (Gelsleichter et al., 2005), whereas
523 this compound was quantified in 100% of samples in our study. The mirex ban and absence
524 of this pesticide in Florida, where it has been widely used in the past (Alley, 1973), suggest
525 recent regional use of this compound in Southern Indian Ocean, possibly to control invasive
526 ants (Blard, 2006; Delabie and Blard, 2002). In the same study, dieldrin concentrations were
527 found to be 10 times higher than in tiger and bull sharks from RUN.
528 Regarding PFASs, little data are available on the accumulation of these emerging pollutants
529 in sharks. Alves et al. (2016) studied blue sharks in Portugal (*Prionace glauca*) and recorded

530 PFCAs and PFOS concentrations 5 times higher than those in sharks from RUN. However,
531 concentrations can be expected to be higher in the Northern Hemisphere, similarly to those
532 of other POPs from industrial sources, such as PCBs. PFASs are more readily-transported in
533 oceans than POPs and are hence likely to be more globally-dispersed throughout the
534 oceans, resulting in smaller differences between hemispheres versus PCBs (Prevedouros et
535 al., 2006).

536 **4. Conclusion**

537 This study provides the first data on the contamination of two shark species collected along
538 the West coast of Reunion Island. Our results showed that POP contamination levels in RUN
539 were lower overall than worldwide levels. PCB and DDT contamination levels were below
540 environmental thresholds, except in bull sharks, which exhibited concentrations of four PCB
541 congeners similar to environmental thresholds.

542 Contamination profiles differed between the two species, indicating, as reported in previous
543 trophic ecology studies, that these two sympatric and opportunistic top predators do not
544 exploit the same trophic niches.

545 Results suggest the presence of PCB sources in Reunion Island, leading to higher
546 contamination levels in bull sharks than in tiger sharks. Tiger sharks were mainly
547 contaminated by OCPs, which are distributed more globally throughout the Indian Ocean,
548 particularly in offshore ecosystems. Contaminant transfer from mother to embryos was
549 species- and contaminant-dependant, suggesting that organic contaminant transfer to
550 offspring is driven by mode of gestation and molecule physico-chemical properties.

551 In view of the limited data available on POPs and CECs in Reunion Island coastal
552 ecosystems, a study on their accumulation in tiger and bull shark preys would be necessary
553 to gain a better understanding of accumulation dynamics. In addition, more investigations
554 would be needed in order to fully understand the maternal transfer of organic contaminants,
555 including CECs, in these species.

556 **Funding**

557 This study was backed by the EURRAICA project, funded by the DEAL/SEB (Regional
558 Council of La Réunion and French State). All studied sharks were caught as part of the
559 PR2P shark control program. M. Chynel received a Master student grant from IFREMER.

560

561 **Acknowledgements**

562 We are grateful to B. Rêche, D. Guyomard, T. Poirout and the fishermen for their support in
563 providing samples. We acknowledge Laura Valentine from “English Assistance for Industry”
564 for the English corrections made to the manuscript. The three anonymous reviewers are
565 gratefully acknowledged for their help in improving the manuscript.

Figure 1: PCB (Σ 30 congeners), DDT (Σ 5 isomers), mirex, dieldrin+endrin, PFCA (Σ 6 compounds) and PFOS concentrations (pg g^{-1} ww) in female bull sharks (BF, n = 11), male bull sharks (BM, n = 6), female tiger sharks (TF, n = 11) and male tiger sharks (TM, n = 10) collected along the West coast of Reunion Island in 2018-2019. Median values (horizontal solid line inside the box), 25th and 75th percentiles (lower and upper ends of the boxes), 95% confidence intervals (whiskers) and outliers (circles) are shown. Box width is proportional to the number of data in each group.

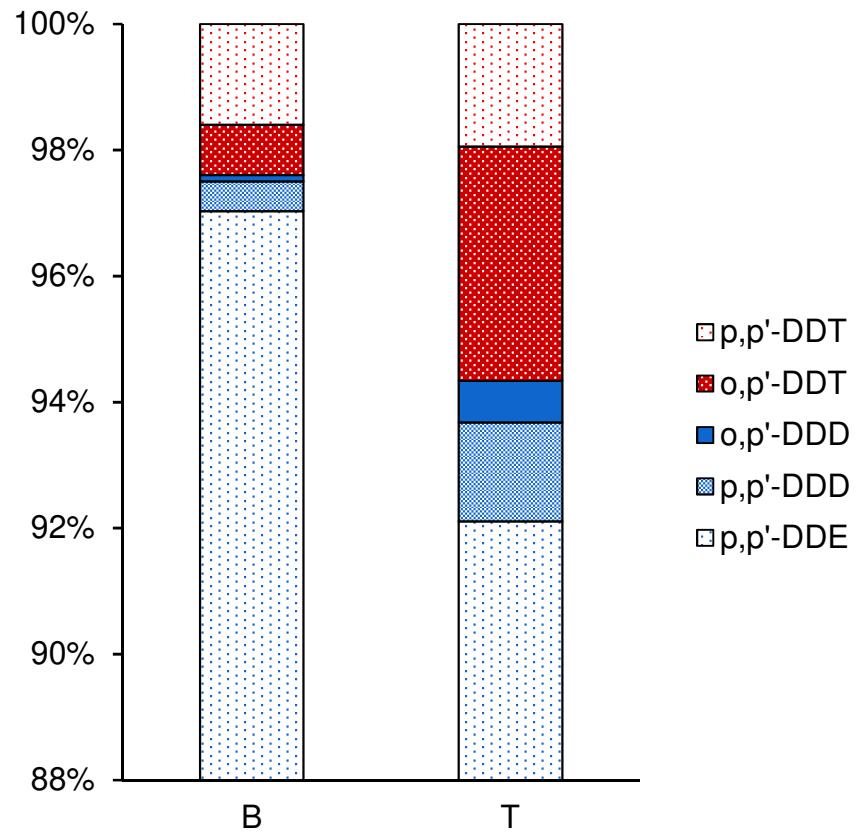

2 columns

Figure 2: Graph of the two principal components of the standardized PCA on the proportions of congeners grouped according to their chlorine numbers and their structure activity group (SAG) (black arrows) in bull shark ($n = 17$; red filled circles) and their embryos ($n = 4$; red empty circles), tiger shark ($n = 21$; green filled triangles) and their embryos ($n = 6$; green empty triangles). The blue circle represents the young-of-the-year (YOY) bull shark. Congener groups represented by blue arrows are misrepresented in this factorial plane and are added for information purposes without being taken into account in the calculations. TriCB: trichlorinated congeners; TetraCB: tetrachlorinated congeners; PentaCB: pentachlorinated congeners; HexaCB: hexachlorinated congeners; HeptaCB: heptachlorinated congeners; OctaCB: octachlorinated congeners; DecaCB: decachlorinated congeners.

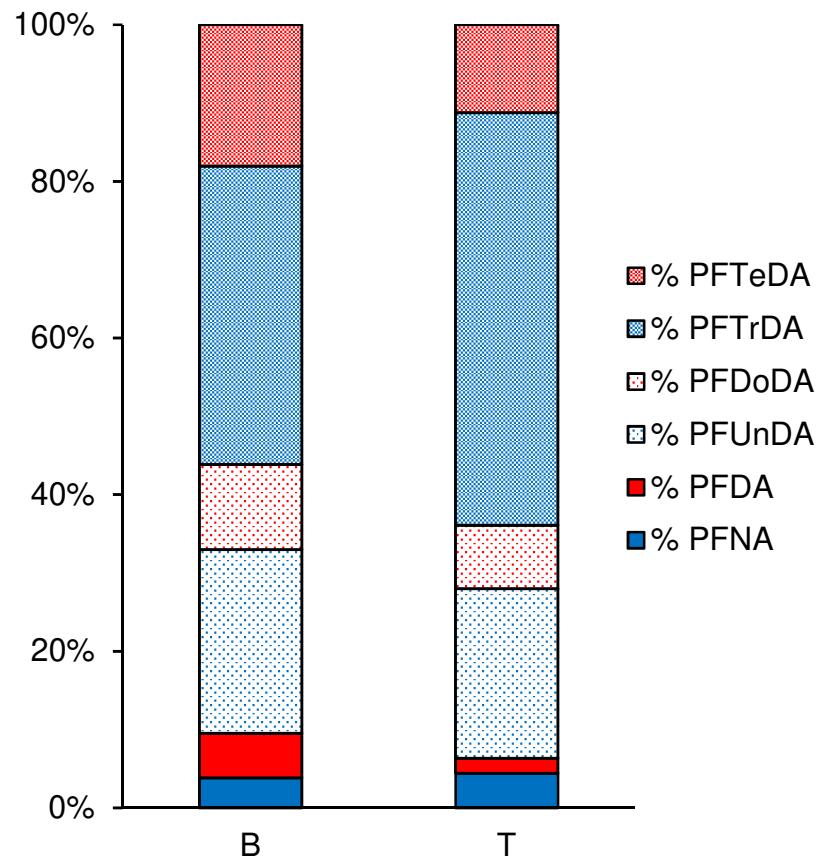

2 columns

Figure 1: Mean DDT contamination profiles (% of the \sum 5 isomers) in bull sharks (B, n = 17) and tiger sharks (T, n = 21) collected in the West coast of Reunion Island in 2018-2019.

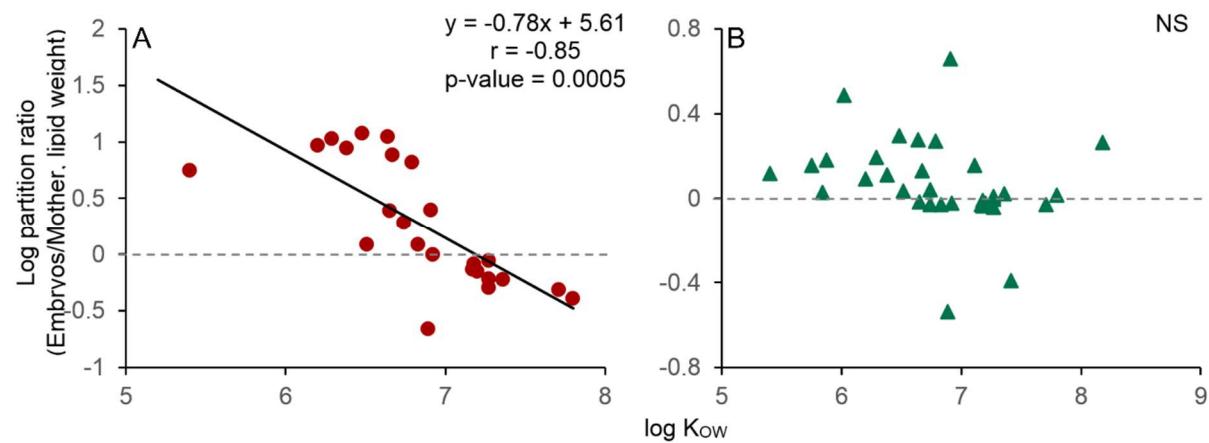

1 column

Figure 1: Mean PFCA contamination profiles in bull sharks (B, n = 17) and adult tiger sharks (T, n = 21) collected along the West coast of Reunion Island in 2018-2019. Odd PFCAs are shown in blue and even PFCAs in red and ranked in ascending carbon number order.

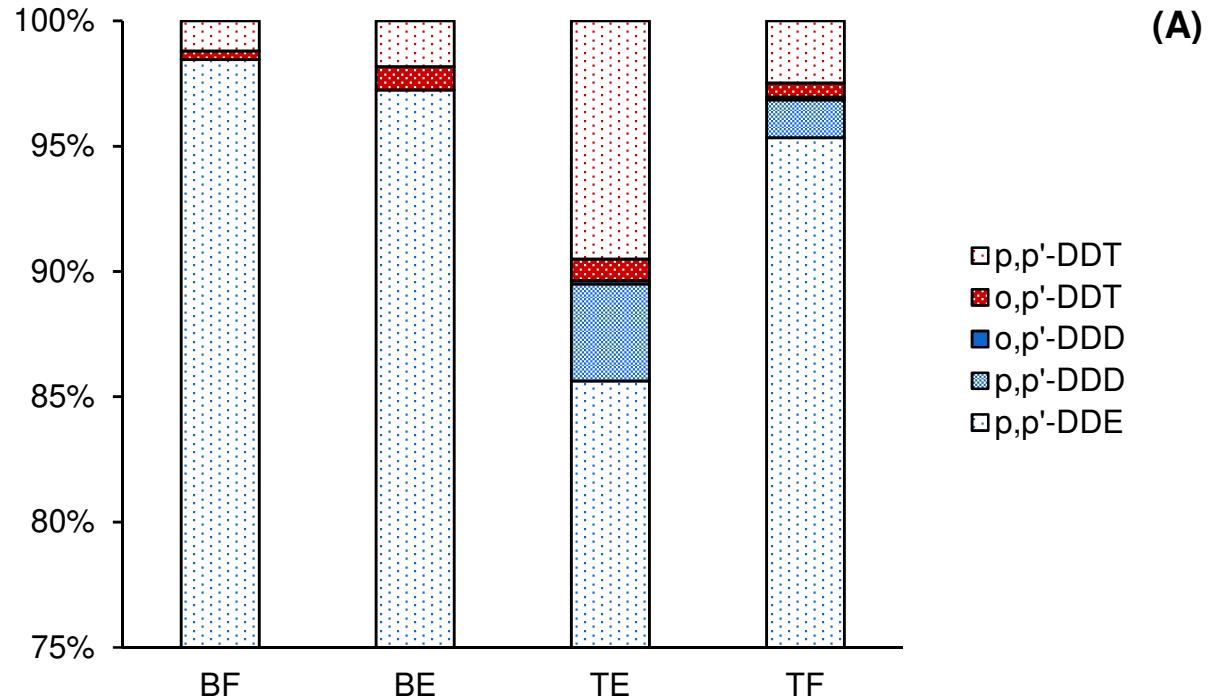

1 column

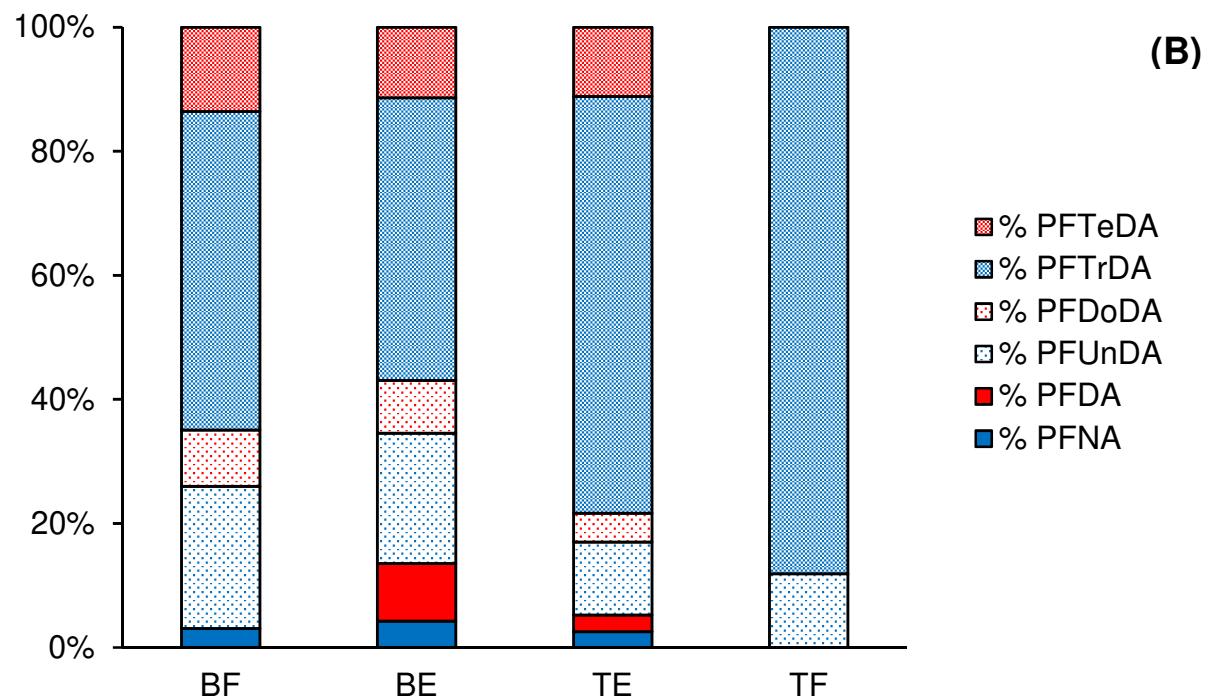

Figure 5: Partition ratios of OCPs and PCBs (pg.g^{-1} lipid weight) plotted against log octanol / water partition coefficient ($\log K_{\text{ow}}$; Hawker and Connell, 1988; Shen and Wania, 2005) in bull sharks (red circles, A) and tiger sharks (green triangles, B). Partition ratios were calculated as mean congener concentrations in embryos relative to the concentrations in the mother and \log_{10} -transformed. Dashed line: partition ratio = 1. NS = non-significant.

2 columns

Figure 6: Mean contamination profiles of DDT (A) and PFCAs (B) in bull shark mother (BF, n = 1), bull shark embryos (BE, n = 4), tiger shark embryos (TE, n = 6) and tiger shark mother (TF, n = 1) collected along the West coast of Reunion Island in 2018-2019. Odd PFCAs are shown in blue and even PFCAs in red. PFCAs are ranked in ascending order of their carbon number.

1 column

Table 1 : Biological parameters (total length: TL (cm); body mass (kg); Fulton's condition factor: K (g cm^{-3}); total lipid content (TLC in % wet weight)) measured in bull and tiger sharks collected along the West coast of Reunion Island in 2018-2019. Data are expressed as mean \pm standard deviation (minimum-maximum).

		Total length (cm)	Body mass (kg)	K (g cm^{-3})	TLC (% ww)
Bull shark	All (n = 17)	231 \pm 57 (160 - 327)	109.2 \pm 74.7 (27.8 - 299.2)	0.74 \pm 0.08 (0.66 - 0.96)	0.57 \pm 0.13 (0.19 - 0.76)
